1. Executive summary

With the expectation that the trophic status of Lake Taupo will slowly change to reflect changes in land use within the lake's catchments, a long term programme to monitor the lake's water quality was commissioned by Waikato Regional Council. This programme commenced in October 1994 and is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office. This report presents the results from the 2012/13 monitoring period.

The monitoring programme was designed to detect change through assessment of the rate of consumption of oxygen from the bottom waters of the lake (volumetric hypolimnetic oxygen depletion – VHOD) as an integration of all biological processes occurring in Lake Taupo. Additional parameters are measured to provide a more comprehensive picture of water quality. Recently it has become apparent that VHOD may be too coarse to determine trophic change in a lake the size and complexity of Lake Taupo. Consequently, more emphasis is now focused on the parameters chlorophyll *a*, water clarity, and nutrient (particularly nitrate) accumulation in the lake.

The long-term monitoring programme uses the historical mid-lake site, Site A. Monitoring of additional sites in the Kuratau Basin (Site B) and the Western Bays (Site C) between January 2002 and December 2004 determined that spatial variability of water quality across Lake Taupo is minimal and that it is valid to use the mid-lake site as representative of the open water quality of the lake. Further validation of the use of a single mid-lake monitoring site was obtained in a separate study over a two-year period from February 2007 up to June 2009, which compared upper water-column nutrient and chlorophyll *a* concentrations and algal species composition with near-shore sites in Whangamata Bay (Kinloch) and Whakaipo Bay. This study determined that “the near-shore water quality was very similar to the mid-lake water quality” and that “within this similarity in the measured data was much variability which may be due to short period time lags between the near-shore and mid-lake sites with respect to nutrient sources, and the zones of algal growth”.

The 2012/13 monitoring period was different from the previous monitoring periods in that it included the eruptions of Mount Tongariro in July and November 2012, and a severe drought in summer 2013. There were indications of numerous hydrothermal events in the bottom of Lake Taupo coinciding with the Mount Tongariro eruptions and associated seismic activity. These external influences may explain some of the variability in the data as well as providing new insight into some lake mechanisms and responses.

Although there is a long-term trend of increasing mean annual phytoplankton biomass (chlorophyll *a*) of $0.013 \pm 0.011 \text{ mg m}^{-3} \text{ y}^{-1}$ in the upper 10 m of water column over the 1994-2013 monitoring period, inter-annual variability in the data was high. As the long-term data accumulates, it has become apparent that the increase in chlorophyll *a* occurred mostly before 2000. The annual mean chlorophyll *a* concentration from 1994 to 2003 increased at a statistically significant rate of $0.087 \pm 0.029 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.001$, $r^2 = 0.857$, $n = 10$), but from 2000 to 2013 there has been an apparent decline at a rate of $0.012 \pm 0.022 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.26$, $r^2 = 0.105$, $n = 14$).

During this monitoring year (2012/13), highest phytoplankton biomass occurred in August 2012 when the lake had mixed and lowest biomass occurred in the upper water column in February 2013, which is consistent with most previous monitoring periods. The pattern of

change in the annual winter phytoplankton biomass maximum also shows an increase from 1994 to the mid-2000s followed by a decline.

Chlorophyll fluorescence profiles show that, each year during summer, a deep chlorophyll maximum (DCM) develops just below the thermocline (40 m). Comparison of the DCM with the upper 10 m layer shows that the chlorophyll *a* concentrations (derived from the fluorescence profiles) can be up to 450% higher in the DCM. Examination of the DCM shows that it forms shortly after winter mixing and has the greatest difference relative to surface values in mid-summer when it may account for more than 70% of the phytoplankton biomass in Lake Taupo.

The 2012 winter bloom was dominated by the diatoms, *Asterionella formosa* and *Fragilaria crotonensis*, each initially accounting for about 40% of the biovolume in the upper 50 m of the water column. *Asterionella* was dominant throughout much of the 2012/13 monitoring period. The dinoflagellates, *Gymnodinium sp.*, *Gonyaulax sp.*, and *Peridinium sp.* increased in abundance through summer 2013 with changing dominance between the three species. Cyanobacteria (blue-green algae) were always present in low numbers in the upper water column throughout the 2012/13 monitoring period, with *Dolichospermum planctonica* (formerly *Anabaena planctonica*) being the most common species, which reached high abundance in November 2012 and February 2013, and then briefly became the dominant species in April 2013.

Nutrient concentrations - dissolved reactive phosphorus, ammoniacal nitrogen, and nitrate nitrogen (DRP, NH₄-N, and NO₃-N) - in the upper water column were comparable with concentrations measured since 2003. NO₃-N concentrations were lower and NH₄-N and DRP concentrations were elevated in the upper water column since 2007. The elevated NH₄-N concentrations may indicate water column decomposition of the winter-spring bloom, or excretion from a zooplankton bloom, but could also be from hydrothermal venting disturbing sediment pore water in the lake bed. Higher than usual DRP and dissolved organic nitrogen (DON) concentrations were associated with hydrothermal events which had most likely disturbed the sediment pore water.

The total mass of NO₃-N in the hypolimnion before winter has increased at a statistically significant rate of about 4.3 t y⁻¹ ($P < 0.05$, $r^2 = 0.15$, $n = 26$) over the last 38 years. This value is slightly higher than the previous year and includes an increase of around 30 t of NO₃-N in the hypolimnion in autumn compared with a decrease of around 70 t in autumn the previous year.

The total mass of NO₃-N in the hypolimnion has experienced a long-term change rising to more than 600 t in autumn 2001 before decreasing again to about 250 t in autumn 2013. While the linear regression through all the data shows a statistically significant rate of increase, these data may be better interpreted as showing a perturbation in the lake, which has now returned to values comparable with those estimated in the late 1970s and early 1980s.

The net accumulation rate of NO₃-N in the hypolimnion below 70 m for the 2012/13 stratified period was 1.50 t d⁻¹, which is around 20% more than in the previous year. However, because of high variability in the data, the increase in the net hypolimnetic NO₃-N

accumulation rate during the stratified period was only weakly significant at 0.026 t d^{-1} ($P = 0.007$, $r^2 = 0.299$, $n = 26$) over the last 38 years.

Although the mass of total nitrogen (TN) in the lake has remained relatively constant at around 3300 t, there was an estimated gain of around 675 t of TN during the 2012/13 monitoring period, compared with a loss of around 920 t the previous year, meaning a small decrease in the total mass.

Spring and summer 2012/13 water clarity was higher than the previous year at over 19 m and reaching 21 m in March 2013. The lower than expected water clarity for the past two years coincided with a relatively wet springs and summers. The higher clarity in summer 2013 and in the summers 2008, 2009 and 2010 all coincided with extremely dry or drought conditions and may reflect lower phytoplankton biomass in the upper water column from the reduced nutrient input in surface runoff as well as a lower input of sediment from erosion.

As observed in 2008, lowest water clarity values in 2012/13 (excluding sediment resuspension due to hydrothermal events) occurred between August and November and were associated with a wet and windy spring. Analysis of the long term data indicates that, between 2000 to 2007, the lowest water clarity was most likely to occur in August but since 2007, the lowest water clarity was more likely to occur in October. This two month shift in water clarity was not accompanied by a comparable shift in the timing of the maximum phytoplankton biomass, indicating that in October the water clarity is most likely affected by suspended sediment from the land. Lowest water clarity occurred in October 2012.

The 2012/13 net VHOD rate at $29.6 \pm 7.1 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) was more than $14 \text{ mg O}_2 \text{ m}^{-3} \text{ d}^{-1}$ higher than the previous year, which was $15.24 \pm 7.38 \text{ mg O}_2 \text{ m}^{-3} \text{ d}^{-1}$. Evaluation of the VHOD data shows that there has been a statistically significant ($P < 0.0001$, $r^2 = 0.74$, $n = 15$) increase of around $1.2 \text{ mg m}^{-3} \text{ d}^{-1}$ in the VHOD rate each year since the low of 1999.

The persistent increase in hypolimnetic oxygen demand over the past 15 years implies a gradual increase in the organic carbon load in the lake since 1999 and is in contrast with steady or decreasing mean annual chlorophyll *a* concentrations in the surface waters and reduction in the annual $\text{NO}_3\text{-N}$ accumulation in the hypolimnion since 2001. An increased hypolimnetic oxygen demand may be the result of higher sediment runoff from land in spring or decomposition of higher phytoplankton biomass in the DCM.

2. Introduction

A long term monitoring programme of Lake Taupo's water quality was commissioned by Waikato Regional Council in October 1994 in the expectation that the trophic state of the lake would change to reflect changes in land use within the lake's catchment. This programme is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office. Various additions and improvements to the monitoring methodology have occurred with advances in available technology, but the core monitoring parameters remain unchanged (Appendix 1). This report presents data from the routine mid-lake monitoring station from July 2012 to July 2013. Additional information for water clarity, temperature, and chlorophyll *a* collected between August 2013 and the time of writing this report has also been included in the data sets in the appendices.

In two earlier reports (Gibbs 2005, 2006), data were included from two additional sites representing those historically sampled in the 1974-76 assessments of lake water quality (White et al. 1980) (Figure 1) to evaluate spatial variability of water quality across the lake. Results from these two additional sites showed that, in general, there were minimal differences between the sites in seasonal variation and that data collected from Site A (mid lake) could be used as representative of the main body of the lake. More recently, a comparison of upper water column nutrient and chlorophyll *a* concentrations and algal abundance was made between Site A and near-shore sites in Whangamata Bay (Kinloch) and Whakaipo Bay (Figure 1), over a two-year period from February 2007 up to June 2009 (Gibbs 2010a). That study determined that, although there were small differences, "the near-shore water quality was very similar to the mid-lake water quality" and the small differences that were observed "may be due to short period time lags between the near-shore and mid-lake sites with respect to nutrient sources, and the zones of algal growth". This report presents data from Site A only.

The monitoring programme has three components: bottom water oxygen depletion, upper water column water quality, and whole water column water quality. Bottom water oxygen depletion is estimated as the volumetric hypolimnetic oxygen depletion (VHOD) rate, which is sensitive to changes in trophic state of lakes that thermally stratify for part of the year (Burns 1995). VHOD is considered a good indicator to detect changes in the water quality of Lake Taupo. Estimates of VHOD are made from dissolved oxygen and temperature profiles measured at 2-3 week intervals during the stratified period. However, the VHOD rate can only indicate changes that may occur in water quality, but not identify their underlying causes. In order to enable understanding of contributing processes, the upper water column (0-10 m depth) is sampled for nutrients, chlorophyll *a*, phytoplankton species composition and water clarity at 2-3 weekly intervals, and full depth profiles are carried out twice during the stratified period. The first profile is taken in spring, when thermal stratification has become established and is stable, the second profile is taken in autumn the following year before thermal stratification begins to break down, as the thermocline deepens.

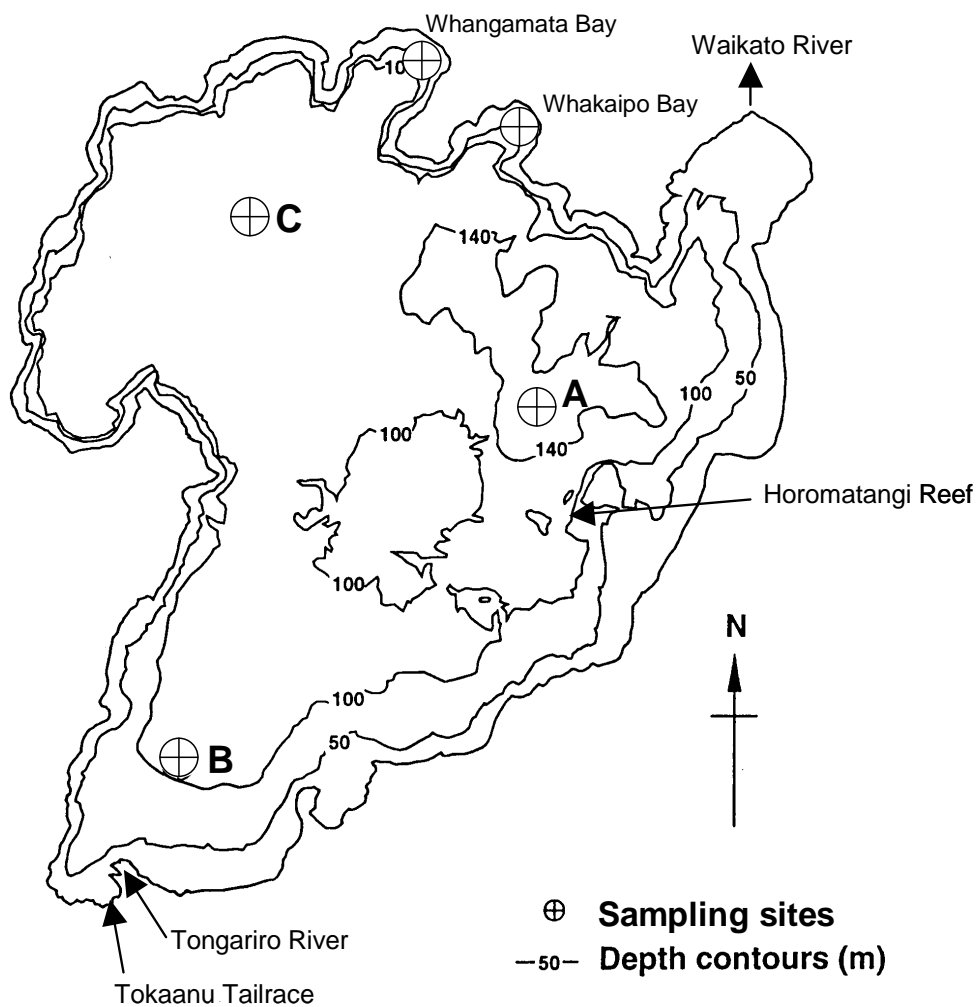

Figure 1: Site map of Lake Taupo. Showing location of the routine monitoring site at mid lake (A), and the two additional sites at Kuratau Basin (B) and the Western Bays (C) sampled during the three-year period 2002-04. The near-shore comparison sites at Whangamata Bay and Whakaipo Bay sampled during a two-year period 2007-09 are also shown.

3. Methods

Detailed method descriptions are given in Appendix 1. The parameters measured routinely at 2-3 weekly intervals are:

- depth-related temperature and dissolved oxygen (DO), using the RBR XR420f CTD profiler until January 2008, thereafter using the RBR XR620f CTD profiling system. Additional parameters of conductivity and chlorophyll fluorescence, and since January 2008, PAR, recorded by the profiler sensors are available at NIWA and will only be reported as appropriate
- water clarity by Secchi disc depth (20-cm black and white quartered)
- chlorophyll *a*, nitrate+nitrite-nitrogen (NO₃-N), ammoniacal-N (NH₄-N), dissolved organic N (DON), particulate-N (PN), dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), and algal species composition and biovolume in integrated-tube water samples from the top 10 m. Concentrations of total nitrogen (TN) and total phosphorus (TP) are estimated by summing the respective measured fractions. Zooplankton net hauls from 100 m (63 µm mesh) are preserved in 4% formalin and stored pending analysis.

Since 2000, water samples have also been collected using a van Dorne water bottle, at the same time, from just above the lake bed (150 m) for analysis of NO₃-N, NH₄-N, and DRP to assess nutrient accumulation rates in the hypolimnion and to assess the extent of winter mixing.

From the 2010/2011 monitoring period on, inclusive, water samples have also been collected by van Dorne water sampler from a depth of 50 m for analysis of chlorophyll *a* to assess the magnitude of the phytoplankton in the deep chlorophyll maximum around the thermocline.

Whole water column sampling is carried out twice a year in spring and autumn and the parameters measured at 10 m depth intervals from the surface down to 150 m depth are:

- Conductivity, pH, temperature, DO, DRP, DOP, PP, TP, NO₃-N, NH₄-N, DON, PN, TN, urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC), and dissolved organic carbon (DOC).

Additional parameters measured twice yearly, but not as complete profiles are:

- Algal species composition and biovolume on water samples from 1, 10, 50, 100 and 140 m.

Details of data handling and the treatment of values that are near analytical detection limits are described in Appendix 1.

3.1 Report contents

This report presents the results from the 2012/13 stratified period plus the winter 2013 mixing, and refers to data in previous annual monitoring reports from 1995 to 2013 (e.g., Gibbs 2013; Gibbs et al. 2002) for inter-annual comparisons, and archived historical data since 1974 held by NIWA. The methods used are as per the 1994/95 report (Gibbs 1995) and a copy of these methods is included in Appendix 1. The calculation of the net VHOD

rate, as applied to Lake Taupo data, was described in the 1996/97 report and a copy of the methods is presented in Appendix 2. Temperature and dissolved oxygen data from the previous nineteen years are given in Appendix 3 and nutrient data are in Appendix 4. Graphical presentations of historical time-series temperature, dissolved oxygen, and Secchi disc depth data collected since the start of this monitoring programme are updated and presented in figures in the text. Phytoplankton species composition and biovolume data for 2012/13 are included in Appendix 5, which holds phytoplankton data since 2006, and are discussed in the text. Historical (before 1994) nitrate and dissolved reactive phosphorus data from spring and autumn full lake profiles are presented in Appendix 6 for reference.

3.2 Statistical evaluation

Simple statistical evaluation of data has been made using Microsoft Excel® and regression results have been reported to $\pm 95\%$ confidence limits. Statistical significance (P), where used, includes the coefficient of determination (r^2) and the number of data points used (n). For details see Statistical Methods, Appendix 1.

3.3 “TREND” definition

As in previous reports, the word “trend” is used in the context of a change between the start and the end of a time series data set where the use of a linear regression analysis shows a statistically significant difference from the null hypothesis of there being no change. Use of the word “trend” is a statistical one. It does not imply any valid extrapolation of the observed change beyond the period of the data set being examined by the linear regression.

4. Results and discussion

4.1 Temperature and dissolved oxygen

The time-series of temperature and DO from 20 m depth (epilimnion) and 130 m depth (hypolimnion) collected in the monitoring programme since 1994 are presented in Figure 2 and Figure 5. Surface values are not used because they are influenced by diurnal warming.

Annual maximum temperatures at 20 m depth are variable between 17 °C and 21 °C, reflecting cooler or warmer summers (Figure 2). The times-series of maximum 20 m temperatures (Figure 3) suggest that there is a cyclical pattern with warmer summers since 2007. Maximum 20 m water temperatures in summer 2013 were about 1 °C warmer than in summer 2012 but were comparable with maximum summer temperatures in the previous four years.

Figure 2: Time-series temperature data. Time-series temperature from 20 m (black line) and 130 m (pink line) depths. Winter mixing occurred where these two lines meet. The data show the lack of mixing in winter 1998 and only partial mixing in 1999 and 2005. Mixing was brief in 1997 and 2010 but strong in 1996, 2002, 2004, 2008, 2009, 2011 and 2012. Data ticks are 1 January each year.

Figure 3: Maximum 20 m temperatures in summer. The trend line is a 5th order polynomial indicating a cyclical pattern.

Despite a cool spring in 2012, temperatures in the upper 20 m were warmer than 19 °C for an extended period from January to April 2013, which is one to two months longer than previously recorded in the 1994-2013 monitoring period. This can be attributed to an unprecedented drought which affected most of the North Island in summer 2013 (Figure 4).

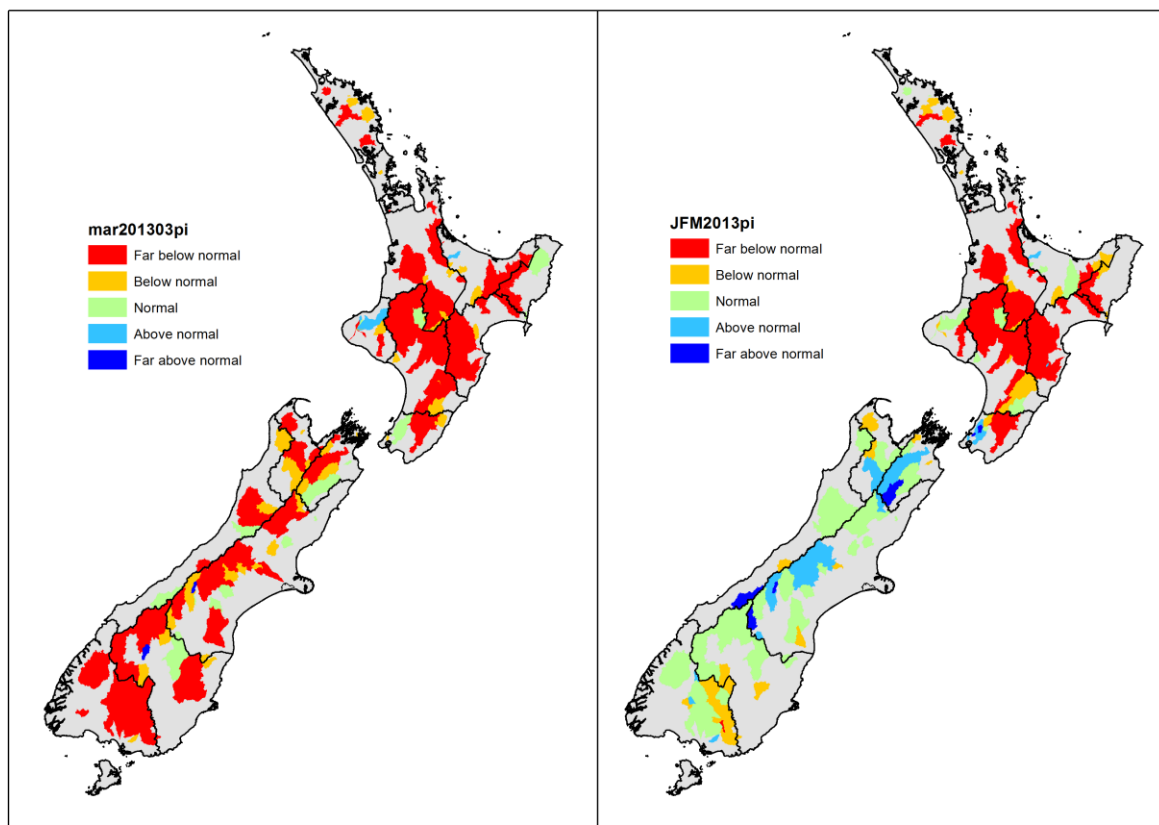

Figure 4: NIWA soil moisture anomaly maps for March 2013 (left) and the period from January to March 2013 (right) showing the extent of the drought. The whole of the Lake Taupo catchment was affected for at least three months.

Near bottom water temperatures have been relatively constant between 10.3 °C and 11.6 °C. Near bottom temperatures slightly increase each year during the stratified period (Figure 2). Winter mixing occurs when the upper and lower temperatures are the same. Mixing rarely extends for more than a month (e.g., winter 2004, Figure 2) during which the whole water column cools rapidly.

Conversely, in some years the period of mixing may be brief or does not occur at all, for instance during winter 1998 (Figure 2) when the bottom water continued to warm throughout winter. The decrease in bottom water temperature during winter is a reasonable indicator of the strength and duration of the winter mixing. In winter 2009, there was a significant decrease in bottom water temperature during winter mixing, suggesting strong mixing for a period of at least a month. In winter 2012 bottom water temperatures decreased during mixing then increased to previous levels as thermal stratification became established.

Even in years with incomplete mixing, the DO content of the hypolimnion rarely fell below 7.0 g m⁻³, even close to the sediment, except in summer 2001 (Figure 5). However, oxygen concentrations close to the sediment were below 7.0 g m⁻³ in 2008 and 2009 and, at the end

of summer 2010, they were below 6.5 g m^{-3} (Appendix. 3). In contrast, during winter mixing in 2008, 2009 and 2011 the bottom water oxygen concentrations exceeded 10.5 g m^{-3} (Figure 5), confirming the high degree of mixing in these years indicated by the colder bottom waters (Figure 2).

Figure 5: Time-series dissolved oxygen data. Time-series dissolved oxygen data from 20 m (black line) and 130 m (pink line) depths. Mixing and reoxygenation occurred where the 2 lines in the temperature data (Fig. 2) meet each winter. However, where temperature data indicate incomplete mixing there is incomplete reoxygenation of the hypolimnion. Date ticks are 1 January in each year.

In summer 2012/13, surface (<20 m) DO concentrations remained above 8 g m^{-3} while bottom water oxygen concentrations were much lower, falling to below 7 g m^{-3} in April 2013 and remaining below 8 g m^{-3} until turnover in early July 2013.

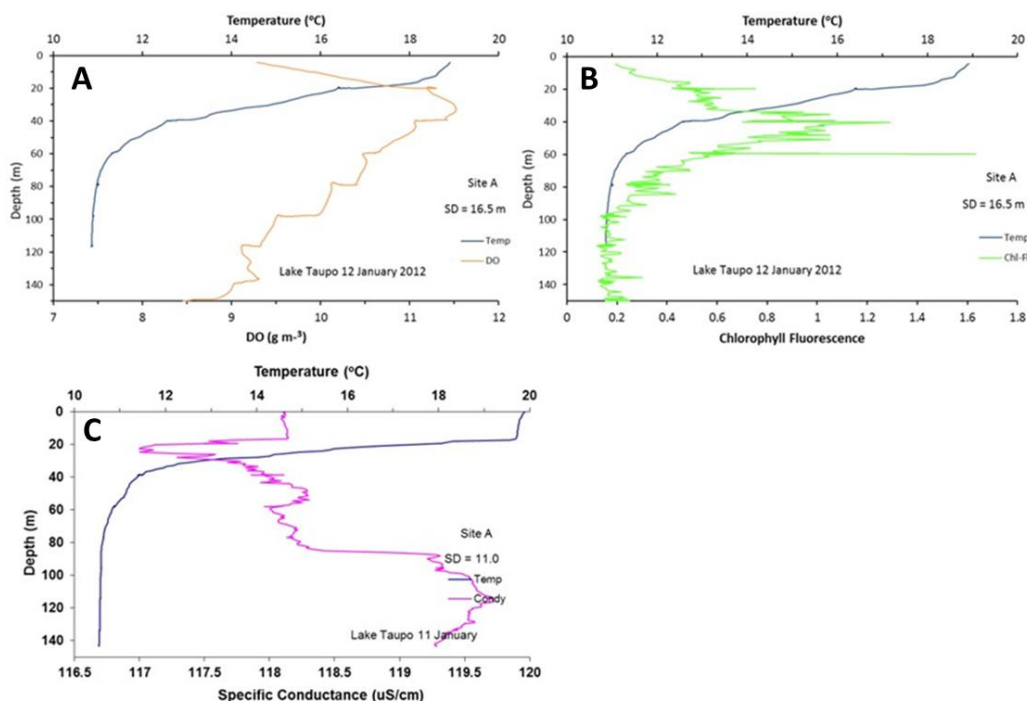

Figure 6: Lake Taupo CTD-O profile examples. A) Dissolved oxygen, and B) Chlorophyll fluorescence in January 2012 and C) conductivity in January 2011 relative to temperature and depth.

Profile data consistently shows DO concentration increases below the thermocline (example Figure 6A) which are associated with photosynthesis in the deep chlorophyll maxima (DCM) (Figure 6B). Photosynthesis in the DCM may be a significant source of DO to the hypolimnion while it is present, but may also be a substantial source of carbon in the water column driving hypolimnetic oxygen depletion when these phytoplankton senesce and decompose.

4.2 VHOD rate

The VHOD rate was estimated between September 2012 and December 2012 based on oxygen profile data collected at site A. VHOD calculations were made using the volume-weighted mean DO concentration below 70 m on each sampling occasion (Figure 7) – see Appendix 2 for more detail. The volume-weighted mean DO concentration stopped decreasing in mid-January 2013 indicating bottom water re-oxygenation was almost balancing sediment oxygen demand at that time. This effect continued at a similar rate through to May. The VHOD rate in 2012/13 was $29.6 \pm 7.1 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) (Figure 7). This value was $14 \text{ mg O}_2 \text{ m}^{-3} \text{ d}^{-1}$ higher than the previous year, which was $15.24 \pm 7.38 \text{ mg m}^{-3} \text{ d}^{-1}$ (Table 1).

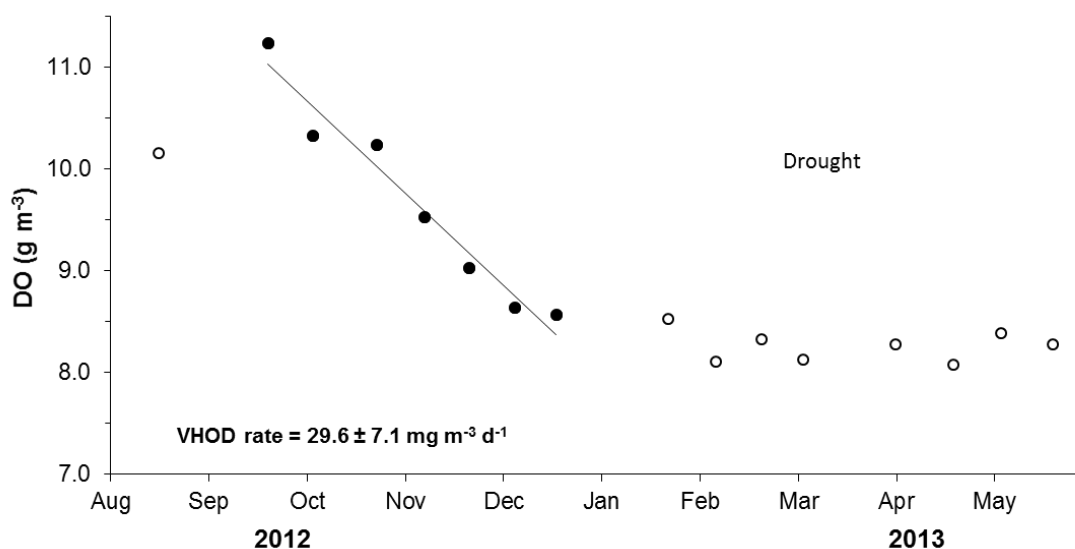

Figure 7: VHOD for 2012-2013 monitoring period. Volume-weighted mean dissolved oxygen (DO) concentrations below 70 m for 2012/13. The slope of the linear regression through the solid data points provides the VHOD rate. ($P < 0.0001$, $r^2 = 0.96$, $n = 7$). Data from January 2013 on show little change indicating re-oxygenation was occurring, balancing sediment oxygen demand.

The 2012/13 VHOD rate was measured between September 2012 and December 2012, a much shorter period of measurement than in the previous years when evidence of reoxygenation became apparent in February. Evidence of reoxygenation in January 2013 is unusual as February is generally the hottest month, the thermocline is strongest. However, a strong thermocline and warm surface waters can induce underflowing density currents from the major river inflows at night when they are much colder than the lake. As the density currents can also entrain oxygenated surface water with the flow, this may be a major cause of the reoxygenation. This has been discussed in detail in earlier reports (e.g., Gibbs 2012).

The VHOD rate was substantially higher than in previous years. Reoxygenation may have occurred from January 2013 on, at a rate sufficient to overcome and balance the hypolimnetic depletion rate until May. The VHOD rate calculated between September 2012 and December 2012 was higher than the VHOD rate recorded in any previous year, including the value of $26 \text{ mg m}^{-3} \text{ d}^{-1}$ estimated by Viner (1989) in the mid-1980s, but with a high error term consistent with the high variability in the data.

Reoxygenation and a high VHOD rate may be associated with climatic effects. The 2011/12 stratified period was longer than normal, extending into September 2012 rather than mixing in July or August. This reflects calmer and milder conditions in winter 2012. This implies a longer period for nutrients to accumulate in the hypolimnion and thus a higher level of phytoplankton stimulation at turnover with a concomitant higher biomass (carbon) to drive the 2012/13 VHOD.

In addition, summer 2013 was the driest year on record for many years, with a severe drought lasting from January to April (Figure 4). These dry conditions would reduce the nutrient runoff into the lake that would normally sustain some level of phytoplankton growth over summer. However, despite high day temperatures the average water temperature from January to May in the lake epilimnion down to 30 m, was not substantially different than the previous three years. Conversely, the clear skies associated with large anticyclone could produce low night time temperatures allowing the temperature of the Tongariro River inflow to fall below the lake bottom water temperature of 11°C , causing the river water to plunge to the bottom of the lake as an under flowing density current. Under these conditions almost all rivers flowing into Lake Taupo will be as under flowing density currents at night and in the morning. Because the cold water from each river is well oxygenated and will entrain several times its volume of oxygenated surface lake water into the density current (Spigel et al. 2005), this mechanism, together with photosynthetic oxygen production in DCM below the thermocline, has the potential to provide sufficient oxygen to substantially off-set or balance the oxygen loss due to sediment oxygen demand, as indicated in the VHOD plot (Figure 7). Consequently, the VHOD calculation cannot include those data.

The low rainfall and associated runoff reduce sediment inputs to the lake and this is seen in the Secchi depth data as high summer water clarity (21 m) in March 2013 and in previous summer low rainfall and/or drought conditions (2008, 2009, 2010, Figure 9). During the day and evening, if the river inflows are cooler than the lake surface temperatures but warmer than the hypolimnion, they are likely to insert as intrusion layers at the depth of the thermocline and the DCM. The higher water clarity in summer allowing deeper light penetration coupled with biologically available nutrients is likely to stimulate growth in the DCM and thus photosynthesis in the upper hypolimnion. This combination is likely to have caused a high spring phytoplankton biomass in the DCM, which would result in elevated water column oxygen demand when the phytoplankton senesced and decomposed leading to a higher VHOD rate in the 2012/13 year.

Another source of carbon in the water column that may affect the VHOD rate is associated with hydrothermal activity in the bottom of the lake. Although there is likely to be continuous low-level activity from the crater vents near the Horomatangi Reef (de Ronde et al. 2002), there are also intermittent larger events, which jet hot ($\sim 300^{\circ}\text{C}$) water up into the lake water column. With these larger events, bottom water and surficial organic sediments can be entrained into the rising hot water plume and may reach the surface waters. The plumes are

seen in the conductivity data as anomalies (Figure 6C) due to elevated salt concentrations in that water. Without the hydrothermal activity, the conductivity profile would closely match the shape of the temperature profile.

The entrained sediment is seen as sudden reductions in water clarity. Being denser than phytoplankton, the resuspended sediment quickly settles once the hydrothermal activity reduces, allowing the water clarity to increase suddenly. For example, in January 2011 the amount of sediment entrained was sufficient to reduce the clarity from a Secchi depth of >18 m to 11 m (Figure 9). This has happened on other occasions (see Secchi depth section 4.3). Several rapid Secchi depth transitions from 18 m to 11 m and back within a few weeks following the initial event are consistent with the occurrence of several larger events in summer. As each event adds organic carbon to the water column, this may increase the rate of oxygen depletion and thus the mean annual VHOD rate.

Conceptually, the more hydrothermal events that occur in a year, the greater the effect on the VHOD rate. During the 2011/12 monitoring period, hydrothermal activity was minimal and there were fewer large events than in the previous few years. This may have contributed to the lower mean annual VHOD rate in 2011/12.

In contrast, the 2012/13 monitoring period had substantial hydrothermal activity. A major hydrothermal event began between 30th May and 14th June 2012 sampling periods and may have been a precursor to the Mount Tongariro eruption on 6 August 2012. Relatively large hydrothermal events continued through spring 2012 and were observed on every sampling profile. A further eruption of Mount Tongariro occurred on 21 November 2012. After this eruption, hydrothermal activity in the lake reduced markedly, although small events were still being observed in January 2013.

It may be coincidental that the highest recorded VHOD rate was observed during an extended period of hydrothermal activity between June 2012 and January 2013 and the apparent reoxygenation of the hypolimnion in the 2012/13 monitoring period was first observed in January 2013 when the hydrothermal activity ceased. Alternatively, decomposition of resuspended organic carbon by hydrothermal activity in the lake might provide another explanation for the high VHOD rate in the 2012/13 monitoring year.

VHOD time series

Assessment of the time-series of changes in VHOD rates shows that there is a statistically significant ($P < 0.0001$, $r^2 = 0.74$, $n = 15$) trend of increase in the VHOD rate data of around $1.2 \text{ mg m}^{-3} \text{ d}^{-1}$ each year since 1999 (Figure 8). The low VHOD in 1999 may be attributed to the effects of the 1995/96 eruption of Mount Ruapehu which deposited around 2 million tonnes of allophanic ash across the lake. While allophane is known to remove phosphate from water, this event also may have triggered a temporary change in the winter bloom dominant algal species from diatoms to buoyant colonial green algae (Table 1). The change from *Aulacoseira granulata*, a heavy diatom which sinks rapidly, to *Botryococcus braunii*, a large colonial green algae which floats in the upper water column, may have allowed the phytoplankton carbon to drift inshore rather than settle in the deeper parts of the lake. As a buoyant algal species, *Botryococcus braunii* behaves much like cyanobacteria in that it drifts with the wind and becomes concentrated along the shoreline and in embayments around Lake Taupo when it becomes dominant. The lower loss of organic carbon to the deep waters could then have resulted in a lower VHOD at that time.

Instead of returning to the pre-eruption VHOD levels after the diatoms again dominated the algal species in the winter bloom, the VHOD rate continued to increase (Figure 8). This sustained increase in VHOD over the past 15 years suggests an increase in the export of organic carbon to the hypolimnion, either from external inputs (i.e., land-use effects), or from internal sources such as enhanced primary production within the lake and resuspension of lake sediments or a combination of both external and internal sources.

Figure 8: Time-series VHOD data. Time-series of VHOD rates since 1994-5. The low VHOD in 1997-2000 (following the 1995/96 eruptions of Mount Ruapehu) correlates with a shift in algal dominance from diatoms to colonial greens (*Botryococcus braunii*). The regression through the solid (red) dots ($P < 0.0001$, $r^2 = 0.74$, $n = 15$), only refers to the change in VHOD since 1998/99, the year when the VHOD rate during the monitoring programme was lowest, and the last year in which diatoms were not dominant. Bars are SD.

Table 1: Summary of VHOD rates. Summary of the volumetric hypolimnetic oxygen depletion (VHOD) rates ($\text{mg O}_2 \text{ m}^{-3} \text{ d}^{-1}$) (\pm 95% confidence limit) and the dominant phytoplankton species during the preceding winter bloom. (* not measured in winter but measured in October 1994).

Year	VHOD rate	Dominant phytoplankton species	Type
1994-95	8.93 (2.39)	<i>Aulacoseira granulata</i> *	Diatom
1995-96	9.07 (2.77)	<i>A. granulata</i>	Diatom
1996-97	5.12 (1.37)	<i>Botryococcus braunii</i>	Colonial green
1997-98	3.21 (2.03)	<i>B. braunii</i>	Colonial green
1998-99	2.64 (1.90)	<i>B. braunii</i>	Colonial green
1999-00	5.11 (1.14)	<i>B. braunii</i> + <i>A. granulata</i> + <i>Cyclotella stelligera</i>	C.G. – Diatom mix
2000-01	9.34 (2.9)	<i>A. granulata</i>	Diatom
2001-02	9.06 (2.7)	<i>Asterionella formosa</i>	Diatom
2002-03	13.76 (2.14)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2003-04	11.50 (2.80)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2004-05	11.30 (1.13)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i>	Diatom
2005-06	9.56 (2.24)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2006-07	10.73 (2.45)	<i>A. granulata</i>	Diatom
2007-08	14.51 (2.94)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i>	Diatom
2008-09	17.50 (3.64)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2009-10	19.21 (1.79)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i> + <i>A. granulata</i>	Diatom
2010-11	17.52 (3.95)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i> + <i>A. granulata</i>	Diatom
2011-12	15.24 (7.38)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i> + <i>A. granulata</i>	Diatom
2012-13	29.6 (7.1)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i>	Diatom

4.3 Secchi depth

Water clarity, as measured by Secchi depth, in Lake Taupo generally follows a seasonal pattern inversely correlating with the pattern of phytoplankton abundance. Secchi depths in the long-term record, until recently (since 2002), have mostly been between 10 m to 20 m (Figure 9). Lowest water clarity occurs during the winter/spring growth phase and highest water clarity during summer when the phytoplankton have settled out of the epilimnion, which is usually depleted in nutrients at that time.

Figure 9: Water clarity as measured by Secchi depth. Time-series Secchi depth data for the present monitoring programme since 1994. Trend line equation $0.060 \pm 0.051 \text{ m y}^{-1}$ ($P = 0.02$, $r^2 = 0.016$ $n = 332$) based on daily data.

The maximum water clarity exceeded 21 m in summer 2012/13 and was comparable with values for the summers of 2008, 2009 and 2010), which also had extremely dry (drought) periods (Figure 9). In contrast, the lower clarity in the summers of 2011 and 2012 was likely to be associated with wetter weather in spring and in summer.

It is possible that the high variability in the clarity data in the current and previous monitoring two years was associated with sediment resuspension from the lake bed, entrained in rising plumes of warm water from a series of hydrothermal eruptions from the bottom of the lake. Sediment detritus particles were observed in the water samples on at least three occasions and there were substantial conductivity anomalies in the profile data. The rapid changes in clarity (Figure 9) are not consistent with patterns of phytoplankton growth and mixing, especially in summer stratification period when the surface waters of the lake have very low phytoplankton biomass. The hydrothermal eruptions ceased in January 2012 and resumed on June 2012, presumably associated with the eruption of Mount Tongariro on 6 August 2012. Once again the water clarity was suddenly reduced as sediment was entrained to the surface. A further eruption of Mount Tongariro occurred on 21 November 2012 after which the hydrothermal eruptions reduced in magnitude but continued intermittently through summer 2013.

Mean water clarity during winter (July – September) has increased by $0.078 \pm 0.082 \text{ m y}^{-1}$ ($P = 0.06$, $r^2 = 0.19$, $n = 19$) since the beginning of monitoring in 1994 (Figure 9). However, this increase has not been consistent over the whole period. Examining the data in 5-yearly blocks shows that the mean winter water clarities for the periods 1995-1999, 2000-2004, 2005-2009 and 2010-2014 were 12.5 m, 13.0 m, 13.5 m and 15.0 m, respectively, whereas the minimum values for each period were 10 m, 9.5 m, 11 m and 9 m, respectively. The monitoring period that is the subject of this report (July 2012- June 2013) was drier than

usual and produced higher mean and minimum water clarities during the mixing period of 16 m and 12.5 m, respectively.

Minimum Secchi depth (1994 to 2013) usually occurs around September (Figure 10). Since 2000 the timing of minimum water clarity may have shifted by two months, from winter to spring (Figure 11). Between 2000 and 2007 the lowest Secchi depth values occurred usually in August but from 2007 to 2013 the lowest Secchi depth values occurred mostly in October. There may be indications that 'winter mixing' is also shifting towards spring with mixing being delayed until September in recent years (see Figure 18). Water clarity in summer was higher after 2007 than before.

Figure 10: Seasonal cycle of water clarity (1994 -2013). The annual pattern of all water clarity data has a seasonal cycle with minimum clarity occurring usually in September.

Figure 11: The timing of minimum water clarity has recently changed. Between 2000 and 2007 (blue), minimum water clarity occurred in winter (August). Since 2007 (red) minimum water clarity has occurred two months later in spring (October). Water clarity in summer was higher after 2007 than before. Curves are 4th order polynomials fitted to the data.

4.4 Phytoplankton

Chlorophyll *a* concentrations tend to be maximum during the winter algal bloom and minimum in summer. As would be expected, there is a statistically significant inverse logarithmic relationship between chlorophyll *a* concentration and Secchi disk depth (Gibbs 2006), although the long-term data suggest that both Secchi depth (Figure 9) and chlorophyll *a* (Figure 12) are increasing.

The previously reported long-term trend of increasing mean and maximum chlorophyll *a* concentrations in the upper 10 m of the water column at the mid-lake site (e.g., Gibbs 2010b), has not changed substantially. With addition of the 2012/13 data, the trend in mean concentration is only weakly statistically significant ($P = 0.07$) (Figure 12) but there is an apparent pattern of an increase followed by a decline in the overall data set (Figure 13).

Figure 12: Time-series chlorophyll a concentrations in the upper 10 m of Lake Taupo. The solid regression line represents a statistically significant increase in the mean chlorophyll a concentrations of $0.013 \pm 0.0107 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P = 0.016$, $r^2 = 0.0175$, $n = 331$). Date ticks are 1 January in each year.

A statistically significant increase in the annual mean chlorophyll a concentrations of $0.087 \pm 0.029 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.001$, $r^2 = 0.857$, $n = 10$) from 1994 to 2003, was followed by a non-statistically significant decrease of $0.012 \pm 0.022 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P = 0.26$, $r^2 = 0.105$, $n = 14$) from 2000 to 2013 (Figure 13).

Figure 13: Annual mean and maximum chlorophyll a concentrations. Annual mean and winter maximum chlorophyll a concentrations from the 10-m tube samples since 1994. Regression lines indicate significant ($P < 0.001$) trends of increase between 1994 and 2003 (broken lines) but weakly significant ($P = 0.075$; maximum) and non-significant ($P = 0.26$; mean) trends of decrease from 2000 to 2013 (solid lines). These regressions overlap between 2000 and 2003. Regression slopes are given in the text. Date ticks are 1 January in each year.

A similar pattern is seen in the annual maximum chlorophyll *a* concentrations with a statistically significant increase of $0.19 \pm 0.086 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.001$, $r^2 = 0.765$, $n = 10$) from 1994 to 2003, and a weakly statistically significant decrease of $0.052 \pm 0.059 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P = 0.075$, $r^2 = 0.240$, $n = 14$) from 2000 to 2013 (Figure 13). The mean of the annual maxima since 2000 was $2.34 \pm 0.1 \text{ mg m}^{-3}$. There was no significant change during the period 1994-2013.

4.5 Deep chlorophyll maxima

The monitoring programme uses chlorophyll *a* concentrations (extracted from integrated tube water samples) as an indicator of phytoplankton biomass in the upper 10 m. However, the use of the profiler fitted with a chlorophyll fluorescence sensor indicates that a large proportion of the phytoplankton biomass in Lake Taupo through spring and summer is associated with the base of the metalimnion (circa 40 to 50 m depth) as a deep chlorophyll maximum (DCM) (e.g., Figure 6B; Figure 14). The DCM typically has a higher proportion of the total phytoplankton biomass than the upper 10 m layer, as demonstrated in Gibbs (2007). The use of a 30-m integrated tube sampler in 1974/75 would have included part of the DCM, accounting for the higher chlorophyll *a* concentrations at that time (Gibbs 2010b). The DCM was present throughout the spring-summer phase of the 2012/13 stratified period with chlorophyll fluorescence (Chl-FI) values comparable with previous years.

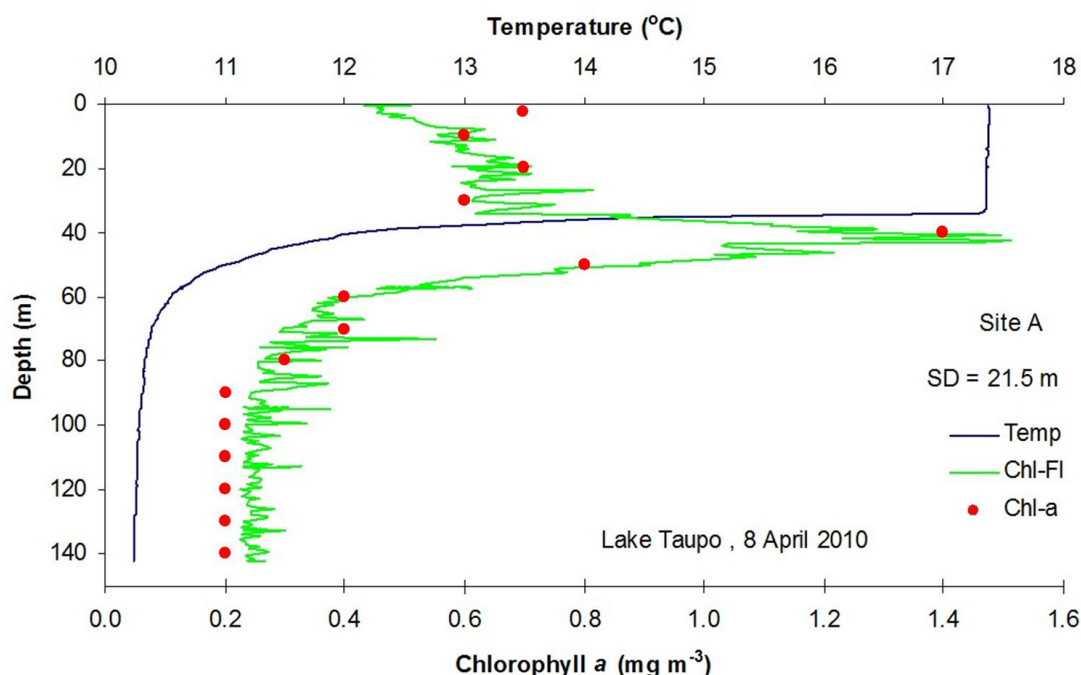

Figure 14: Deep chlorophyll maxima. Example of a deep chlorophyll maxima in Lake Taupo measured by chlorophyll fluorescence (Chl-FI) on 8 April 2010 compared with extracted chlorophyll *a* (Chl-*a*) concentrations (red dots) from water samples collected at 10 m depth intervals on the same day. The peak phytoplankton biomass lies just below the thermocline.

The chlorophyll fluorescence profile data can be converted to chlorophyll *a* concentrations by calibration against extracted chlorophyll *a* data from discrete water samples collected from selected depths. Below 20 m depth, the resulting chlorophyll *a* concentrations estimated by the fluorescence profiler are typically within 5% of concentrations measured by extraction from the discrete water samples (Figure 14). However, above 20 m, fluorescence quenching

by sunlight means the fluorescence data cannot be used directly and a correction curve is derived by regression to provide estimates closer to the surface. Differences between the two estimates below 80 m depth (Figure 14) are probably due to reporting the analytical results to one decimal place.

Comparison of the chlorophyll *a* concentrations in the DCM, estimated from chlorophyll fluorescence profile data calibrated against extracted chlorophyll *a*, with those in the upper 10 m for the last 5 years shows that the greatest concentration of biomass typically occurs during winter, both for the surface and for the DCM (Figure 15A). The greatest difference between the two water layers, as a % of the surface concentration, occurs during summer. (Figure 15B), These data also show that there is some level of DCM is present throughout the year except during winter mixing, prior to the surface peak in chlorophyll *a*.

While the time-series DCM chlorophyll *a* concentrations (Figure 15) are the maximum values for the phytoplankton biomass around the thermocline, often the DCM peak is broad encompassing a 20 m to 40 m thick layer (Figure 14; Figure 16). Consequently, the DCM can contain a high proportion of the total phytoplankton biomass in the lake. On occasion this may be more than 70% of the total phytoplankton biomass.

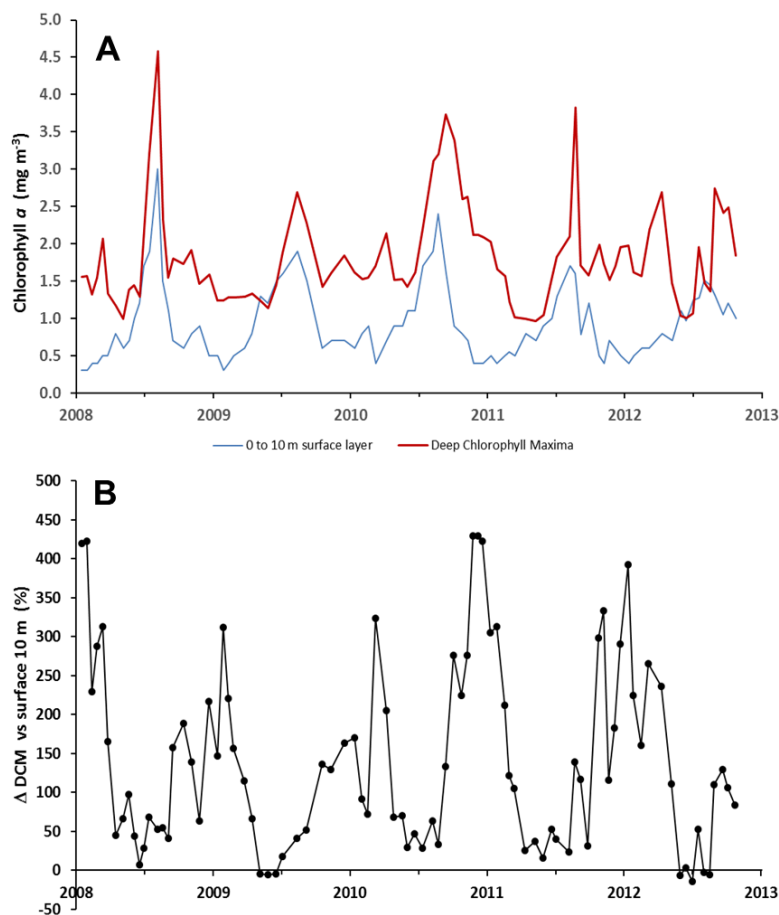

Figure 15: DCM data from 2008 to 2012. A) Comparison of chlorophyll *a* concentrations in the 0 to 10 m layer and the chlorophyll *a* in the DCM layer calculated from calibrated chlorophyll fluorescence profiles, and B) The difference between the DCM and the 0 to 10 m depth layer, as a percentage of the surface concentration.

Time-series chlorophyll fluorescence profile data also provide an insight as to how the phytoplankton biomass (and thus the particulate nutrients) are distributed through the water column over the summer to the winter mixing period (Figure 16). For example, in 2010 the February and April profiles show the DCM as a narrow band centred between 40 and 50 m. The June profile shows that wind mixing had dispersed the phytoplankton biomass through the epilimnion. In July epilimnetic phytoplankton biomass had increased and moved down with the thermocline leaving less phytoplankton biomass near the surface. In September, after winter mixing, the phytoplankton biomass had increased even more but was settling down through the whole water column.

While photo quenching of the chlorophyll fluorescence signal occurs during summer because of the high solar radiation levels, the effect is less pronounced during winter months because the sun is at a lower angle and less intense. Consequently, the chlorophyll fluorescence profiles follow the chlorophyll *a* data more closely. Although the phytoplankton biomass is settling through the water column in September, turbulence can hold part of that biomass high in the water column and this forms the core of the DCM when thermal stratification begins in October.

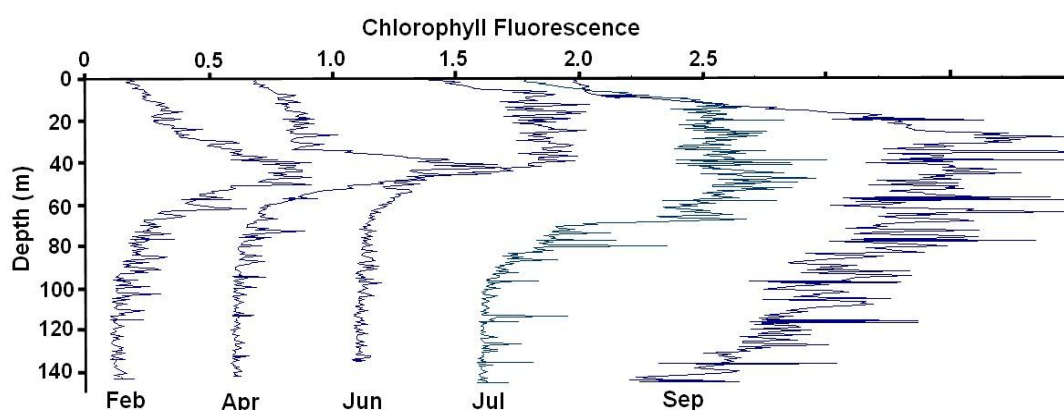

Figure 16: Fluorescence profiles in Lake Taupo. Selected sequential chlorophyll fluorescence profiles during 2010 showing the progression from a deep chlorophyll maxima in summer to its disappearance and sedimentation of algal matter during the winter bloom. Each profile is offset to the right by successive 0.5 chlorophyll fluorescence units for clarity.

4.6 Algal species abundance

In winter-spring 2012, the algal species assemblage was dominated by the diatoms *Asterionella formosa* and *Fragilaria crotonensis*, each accounting for about 40% of the biovolume in the upper 50 m of the water column. *Asterionella* became the dominant species in late August 2012 through the remainder of the year accounting for more than 65% of the biovolume. While *Botryococcus braunii* was present through summer, cell numbers were very low. Dinoflagellates, including *Gymnodinium sp.*, *Gonyaulax sp.*, and *Peridinium sp.*, in varying abundance, increased through summer becoming co-dominant with *Fragilaria* on occasion. Cyanobacteria, mainly *Dolichospermum planctonica* (formerly *Anabaena planctonica*) were frequently present in the surface waters at low abundance and biovolume throughout much of the 2012/13 monitoring period and reached high abundance in November 2012 and in February 2013, when it appeared to be dispersed through the water column down to 50 m, and April 2013, when it briefly became the dominant species in the surface waters.

In spring, the deep chlorophyll maximum at a depth of 50m (van Dorne sample) was dominated by *Asterionella formosa* with *Aulacoseira granulata* as a minor component of the algal assemblage until October when *Asterionella* became the dominant species. *Asterionella* remained the dominant species in the DCM throughout the remainder of the 2012/13 monitoring period with other species settling from the upper water column. The exception was in February 2013, when *Dolichospermum* was the dominant species in the DCM. There was considerable variability in the biovolume in the DCM sample relative to the 0 to 10 m samples, ranging from more than double to half the biovolume in the 0 m to 10 m. This is due to the van Dorne sampler not always collecting water from the centre of the DCM peak.

4.7 Nutrients in the upper waters

The 2012/13 concentrations of DRP (Figure 17A), NH₄-N (Figure 17B), NO₃-N (Figure 17C) and DON (Figure 17D), were within the range of previously measured values, except for DRP, which had some unusually high values. As previously noted (Gibbs 2006), nutrient concentrations decreased abruptly at the time of the Mount Ruapehu eruptions in 1995 and slowly returned to pre-eruptions levels (Figure 17). Since 2003, maximum concentrations of NO₃-N and NH₄-N in the surface layer (Figure 17B and C) have mostly coincided with winter mixing periods when vertical mixing returns nutrients from bottom waters to the surface layer. Higher DRP concentrations have also been observed during winter mixing in 2009, 2011 and 2012 (Figure 17A).

The unusually high DRP value occurred in April 2013 and coincided with a larger than usual hydrothermal eruption event as indicated by an extended anomaly at that time. Similar spikes in DRP concentration also occurred during spring 2012 (Figure 17A) also coinciding with the more vigorous hydrothermal activity in the bottom of the lake associated with the Mount Tongariro eruptions.

The NH₄-N concentrations in the upper water column have been relatively elevated since the beginning of 2007 compared with period from 2003 to 2007 (Figure 17B). NH₄-N usually appears in the surface water at the time of winter mixing and can be attributed to upwelling of nutrient-rich bottom water. However, occasionally elevated NH₄-N concentrations occur at other times through the year not linked to upwelling events. Elevated NH₄-N concentrations during the stratified period may be the result of microbial decomposition of senescing phytoplankton or excretion by zooplankton which have grazed the phytoplankton to a low biomass in the surface waters (Figure 12). The reason for low phytoplankton biomass may be associated with the dominance of the phytoplankton assemblage by diatoms which are likely to sink during extended periods of calm conditions that occur over summer.

Another potential source of NH₄-N may be associated with hydrothermal activity in the bottom of the lake. Geothermal waters often have a high concentration of NH₄-N.

During the 2008/09 monitoring period, DON concentrations fell below the long-term minimum value of around 29 mg m⁻³ for the first time since the beginning of the monitoring programme. It has been assumed that the minimum amount of DON consists of refractory organic material. During the 2010/11 monitoring period, DON concentrations also fell below 29 mg m⁻³ during September and October before increasing to more typical values of 40 to 50 mg m⁻³. Increases above 60 mg m⁻³ coincided with hydrothermal eruption events as indicated by conductivity anomalies observed in the CTD profile data. DON concentrations were above

the long-term minimum value throughout the 2012/13 monitoring period and often exceeded 60 mg m^{-3} , especially during the Mount Tongariro eruptions.

Hydrothermal event mechanism

Labile DON is an intermediary product of the decomposition processes occurring in the sediment. DON accumulates in the sediment pore water where it is further mineralised to $\text{NH}_4\text{-N}$ and can be nitrified to $\text{NO}_3\text{-N}$. DRP mineralised from organic matter also accumulates in the sediment pore water. Hot water rising to the surface during a hydrothermal eruption event entrains bottom water, including surficial sediment and pore water, bringing it to the lake surface. This may explain the sudden increase in epilimnetic nutrient concentrations from time to time (Figure 17) which would imply entrainment of hypolimnetic water may be a mechanism for pumping nutrients into the epilimnion of Lake Taupo without a full mixing event.

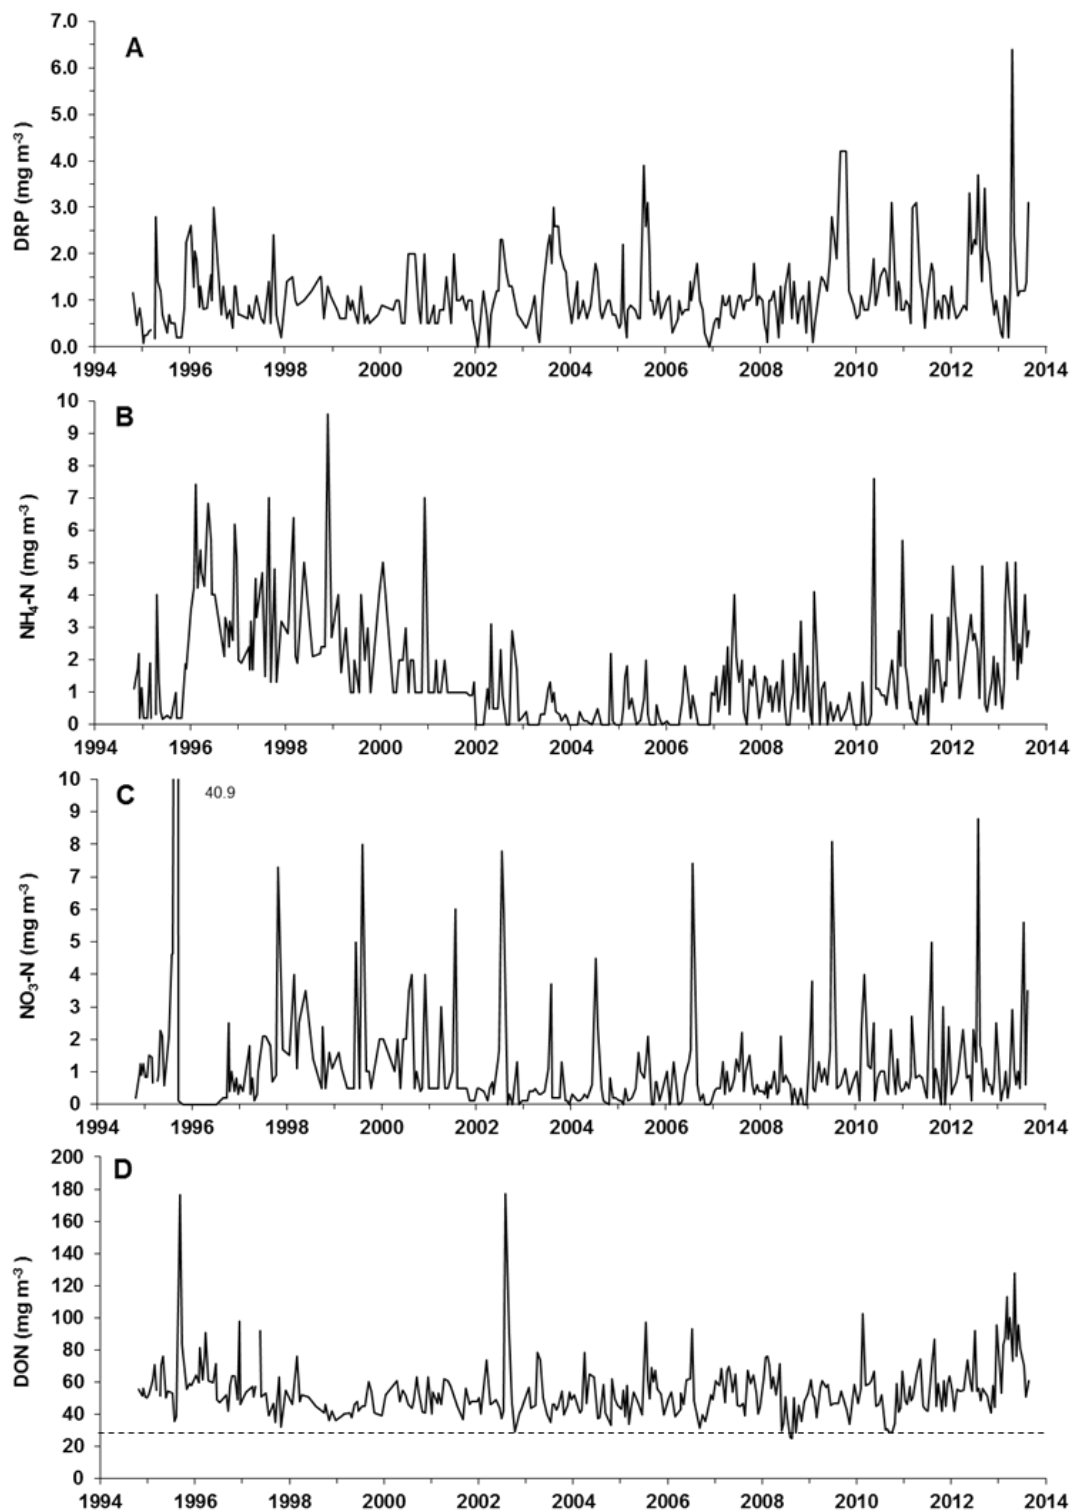

Figure 17: Time series nutrient data in Lake Taupo. Time series data from the top 10 m of the water column in Lake Taupo for (A) dissolved reactive phosphorus (DRP), (B) ammoniacal nitrogen ($\text{NH}_4\text{-N}$), (C) nitrate + nitrite nitrogen ($\text{NO}_3\text{-N}$), and (D) dissolved organic nitrogen (DON). Broken line indicates the long term minimum DON concentration of 29 mg m^{-3} , which may be mostly refractory organic material. Date ticks are 1 January in each year.

From conductivity anomalies in the CTD profile data, hydrothermal eruption events are relatively common in Lake Taupo. That the time-series data do not show a large peak on each occasion may be due to pore water depletion during frequent or extended eruptions, or the sampling frequency, which may not coincide with a hydrothermal eruption event.

Except during winter mixing, $\text{NH}_4\text{-N}$ concentrations in the hypolimnion are usually very low ($<1 \text{ mg m}^{-3}$) due to high rates of nitrification at the sediment–water interface and in the water column (Vincent & Downes 1981). A loss of benthic and planktonic nitrifiers associated with the volcanic ash from the Mount Ruapehu eruptions in 1995/96 may explain the absence of $\text{NO}_3\text{-N}$ and the elevated $\text{NH}_4\text{-N}$ concentrations in the epilimnion for about a year after the eruption (Figure 17B and C).

4.8 Nutrient accumulation in the hypolimnion

Dissolved inorganic nutrients in water samples from 150 m depth demonstrate consistent seasonal patterns driven by the mixing in winter (Figure 18). A sudden drop in DRP and $\text{NO}_3\text{-N}$ concentrations usually occurs around the beginning of August as a result of winter mixing. In 2008 and 2009 mixing began in mid to early July but, did not occur until late September 2010, and the mixed period was brief (Figure 2). Winter mixing in 2012 occurred in early September and stratification was re-established at the beginning of November 2012. The DRP concentrations increased rapidly reaching substantially higher concentrations than in the previous 10 years (Figure 18). In the 2012/13 monitoring period, the lake remained stratified until early August 2013. Despite this reduced period of accumulation, DRP concentrations were around 25% higher than in previous years (Figure 18). This may also be an effect of the sustained hydrothermal activity during spring 2012 disturbing the sediment pore water (see “**Hydrothermal event mechanism**” note above).

Figure 18: Time series bottom water nutrient data. DRP , $\text{NO}_3\text{-N}$ and $\text{NH}_4\text{-N}$ concentrations in the bottom waters (150 m depth) of Lake Taupo since winter mixing of 2004. (Starting tick “J” = June with 3-monthly increments).

Hypolimnetic $\text{NO}_3\text{-N}$ concentrations before the onset of winter mixing have been consistently around $32\text{-}35\text{ mg m}^{-3}$ since 2004, after declining from a maximum of 46 mg m^{-3} in 2001. The 2012/13 results for $\text{NO}_3\text{-N}$ also follow this pattern (Figure 18), although $\text{NO}_3\text{-N}$ concentrations were higher than in the previous four years. During each brief mixing period, $\text{NH}_4\text{-N}$ is released into the bottom water (Figure 18), but its maximum concentration has decreased from around 9 mg m^{-3} in 2001 to about 3.4 mg m^{-3} during mixing in winter 2012. The source of this $\text{NH}_4\text{-N}$ is not clear but it may be derived from pore water in the sediment, which would be disturbed by the mixing currents associated with the winter mixing event.

4.9 Total mass accumulated

The total mass¹ of $\text{NO}_3\text{-N}$ in the hypolimnion (below 70 m depth) in autumn each year before the onset of winter mixing has ranged from about 120 t (1978) to more than 650 t (1999) (Figure 19). While this graph is similar to those in earlier reports, it also includes additional information from historical data sets held by NIWA. The historical data used to produce the additional data points from 1975 to 1990 are given in Appendix 6. Since 1975 there has been a statistically significant ($P < 0.05$, $r^2 = 0.15$, $n = 26$) increase in the total mass of $\text{NO}_3\text{-N}$ of around 4.3 t y^{-1} in the hypolimnion before winter mixing (Figure 19).

Figure 19: Total mass of $\text{NO}_3\text{-N}$ in the hypolimnion of Lake Taupo in autumn before winter mixing. The linear regression (solid line) indicates a statistically significant increase of 4.3 t y^{-1} ($P < 0.05$, $r^2 = 0.15$, $n = 26$). Temporal changes in the data are better described by a 3rd order polynomial (dashed line) ($r^2 = 0.556$) which accommodates a rise and fall in the data over the monitoring period since 1974. Open circle data were excluded from regression as time periods and sampled depths were not the same as used for the other data. Date ticks are 1 January in each year.

¹ In earlier reports the total mass of $\text{NO}_3\text{-N}$ in the hypolimnion each year has been referred to as the “total accumulated mass” of $\text{NO}_3\text{-N}$. It is the “standing stock” of $\text{NO}_3\text{-N}$ at that time

The total mass of NO₃-N in the hypolimnion in April 2013 was around 246 t, an increase of around 34 t since 2012, but still within the range of inter-annual variability in the recent data (Figure 19).

The use of a linear regression through the data does not indicate that a change in the amount of NO₃-N accumulating in the hypolimnion occurred around 2000, at which time the annual amount that accumulated began to decrease. The resultant time-series of annual total mass accumulated data are better described by a 3rd order polynomial ($r^2 = 0.556$) than a linear regression ($r^2 = 0.15$).

Alternatively, these time series data could be described by three linear regressions (Figure 20). From 1975 to 1996 there was a non-significant increase of $4.37 \pm 0.03 \text{ t y}^{-1}$ ($r^2 = 0.27$, $P = 0.15$, $n = 9$); from 1996 to 2000 there was a period of significant increase at $96.3 \pm 51.4 \text{ t y}^{-1}$ ($r^2 = 0.92$, $P < 0.01$, $n = 5$); and from 2000 to present, there was a period of significant decrease at $23.4 \pm 12.4 \text{ t y}^{-1}$ ($r^2 = 0.66$, $P < 0.001$, $n = 14$). The shift from an increase to a decrease around 2000, is also seen in the chlorophyll a data (Figure 13). While the change in the chlorophyll a maximum can be explained as a response to the change in the amount of NO₃-N released at winter mixing, the cause of the change in the amount of NO₃-N released is not known. Whatever the cause, total mass of NO₃-N in the lake hypolimnion in the 2012/13 monitoring period is comparable with the mass present in the lake 1970s and early 1980s.

Figure 20: Changes in nitrate (NO₃-N) accumulation in the hypolimnion of Lake Taupo. The last regression line shows that in the last 14 years, NO₃-N mass has decreased at a significant average rate of around 23 t y^{-1} ($P < 0.001$, $r^2 = 0.66$, $n = 14$) and is now comparable with the estimated mass present in the late 1970s and early 1980s.

4.10 Net accumulation rate

The total mass of $\text{NO}_3\text{-N}$ in the hypolimnion before winter mixing is the sum of the mass of $\text{NO}_3\text{-N}$ in the hypolimnion at the beginning of the stratified period and the net mass that was released from the sediments as well as from decomposing plankton that accumulated in the hypolimnion during the stratified period. There will also be some assimilation of $\text{NO}_3\text{-N}$ by phytoplankton in the DCM during spring but, because the net accumulation rate calculation uses data below 70 m (20 m to 30 m below the DCM), this effect may be minimal. The difference between the standing stock of $\text{NO}_3\text{-N}$ at the beginning and end of the stratified period is the net mass of $\text{NO}_3\text{-N}$ accumulated in the hypolimnion.

To determine the net accumulation rate of $\text{NO}_3\text{-N}$ in the hypolimnion, the total mass data below 70 m depth (Figure 19) have been transformed into accumulation rate data by subtracting the mass present in spring from the mass present in autumn and dividing by the number of days between the spring and autumn samplings (Figure 21).

Mineralisation and release of nutrients from the sediments are driven by microbial processes that are a function of temperature and dissolved oxygen concentration. As the hypolimnion is well oxygenated and the temperature remains constant within ± 0.3 °C, a fairly constant rate of net accumulation is expected throughout the stratified season unless inputs change. There was a weakly significant increase in the net accumulation rate of 0.020 ± 0.024 t d^{-1} per year ($P = 0.1$, $r^2 = 0.108$, $n = 26$) since 1975 (Figure 21), which was similar to the previous report. The data for 1976 and 1987 were excluded from the regression analysis because they were estimated using different periods than the rest of the data (see also Figure 19). The data points for 1976 and 1987 are included in Figure 21 as an indication of what the net accumulation rates may have been in those two years.

Figure 21: Net Hypolimnetic $\text{NO}_3\text{-N}$ accumulation rates. Net $\text{NO}_3\text{-N}$ accumulation rates (t d^{-1}) in the hypolimnion below 70 m. The regression line shows an increase in the net accumulation rate of 0.020 ± 0.024 t d^{-1} ($P = 0.1$, $r^2 = 0.15$, $n = 26$). Open circle data were not included in the regression analysis (see text). Note that the Y-axis extends to -0.5 t d^{-1} for the 2006 data point. Date ticks are 1 January in each year.

The net accumulation rate for the 2012/13 period was 1.50 t d^{-1} , which was about 20% higher than the previous year (1.23 t d^{-1}). The time-series of net accumulation rates of $\text{NO}_3\text{-N}$ (Figure 21) show a high degree of variability between years, with the 1999 and 2006 data points falling well below the trend line. The negative net accumulation rate in 2006 indicates a net loss of $\text{NO}_3\text{-N}$ from the hypolimnion during the 2005-06 stratified period. Both of these data points are for years following a winter where there was incomplete mixing. This suggests that those two low values are anomalies relative to the rest of the data. The effect of incomplete mixing was discussed in an earlier report (Gibbs 2007). Excluding those two values, the net accumulation rates of $\text{NO}_3\text{-N}$ shows a highly significant increase of $0.026 \pm 0.018 \text{ t d}^{-1}$ ($P < 0.007$, $r^2 = 0.299$, $n = 23$) with the regression line rotating closer to the early (1975 and 1978) data.

4.11 Total N

Total nitrogen (TN) mass in Lake Taupo was estimated from the spring profile in each year. There was no statistically significant trend in the total mass of TN (Figure 22). The mean was 3294 t, contrasting with a net total annual external TN input to the lake of around 1000 t (W. Vant, Waikato Regional Council, pers. comm.). The total mass of TN in Lake Taupo in spring 2012 was 2895 t, 675 t more than in the previous year. Note there was total mass loss the previous year of 920 t meaning the increase in 2012/13 is still part of a decrease in the mass of TN in the lake.

Figure 22: Estimates of the mass of total nitrogen (TN) in Lake Taupo. Although there was an average decrease of about 3.8 t y^{-1} from 1975 to 2013, this apparent trend in the data is not statistically significant ($P = 0.79$, $n=24$, $r^2 = 0.003$). The mean was 3294 t. Date ticks are 1 January in each year.

5. Knowledge gaps

1. An earlier report (Gibbs 2006) listed several knowledge gaps including in-lake processes in Lake Taupo, and process rates at the sediment-water interface. This report presents estimates of the net rate of $\text{NO}_3\text{-N}$ accumulation in the hypolimnion during the stratified period as well as estimates of the net efflux of inorganic nitrogen from the sediments. Together these data indicate that the net $\text{NO}_3\text{-N}$ accumulation rates in 1999, and 2006 may be anomalous. These years have in common that they followed a year of incomplete mixing in winter. The immediate return of the net accumulation rate to the trend in the net accumulation rate data the following year, points to water column processes being as important as sediment processes for controlling hypolimnetic $\text{NO}_3\text{-N}$ concentrations and highlights the need to understand how the water column processes work in Lake Taupo.
2. The sum of the external inputs to the lake from the catchment via rivers and atmospheric deposition minus the mass lost from the lake via the Waikato River is estimated to be around 1000 t y^{-1} (W. Vant, Waikato Regional Council, pers. comm.). Despite this net input of TN, which represents around a third of the average mass of N in the lake (3300 t), there is no significant increase in the long term TN in the lake (Figure 22) and the data indicate small, non-statistically significant decrease in TN content over the study period from 1994 to 2013.

The total mass of $\text{NO}_3\text{-N}$ in the hypolimnion just before winter mixing each year appears to reach a plateau (see shape of $\text{NO}_3\text{-N}$ concentration curves, Figure 19). This may be explained by diffusion across an increasing concentration gradient in the metalimnion or assimilation by algae in the DCM.

Together these data suggest that processes at the sediment-water interface and elsewhere in the hypolimnion are capable of sequestering a very large amount of N each year. However, the net increase in accumulation rate of $\text{NO}_3\text{-N}$ in the hypolimnion suggests that the sediment processes of nitrogen burial, decomposition, mineralisation, nitrification, denitrification and assimilation are changing.

We have little or no information on any of these N transformation and sequestration process rates in Lake Taupo.

3. The appearance of $\text{NH}_4\text{-N}$ along with higher concentrations of DRP in the upper water column during late spring and summer in since 2007, is unusual as these nutrients are usually rapidly assimilated in Lake Taupo by phytoplankton. The source of the epilimnetic $\text{NH}_4\text{-N}$ and DRP is unknown.
4. In February 2010, January 2011 and June - December 2012 sampling coincided with hydrothermal eruption events in the lake floor (e.g., Figure 6) and the eruption of Mount Tongariro in 2012. These events brought sediment to the lake surface (personal observation) together with pulses of $\text{NO}_3\text{-N}$, DON and possibly DRP. These nutrients are presumed to have come from sediment pore water. These observations suggest that these periodic hydrothermal events bring additional nutrients into the upper water column. Also, it is not clear whether there are nutrients in the geothermal sources in the lake bed and whether they have a significant role in the nutrient budget of the lake. Recent increase in hydrothermal activity may be responsible for episodic increases in epilimnetic nutrient concentrations. More information is required on how hydrothermal eruption events affect the water quality of Lake Taupo.

5. The mean annual water clarity and the mean annual chlorophyll *a* concentrations in the upper 10 m of the water column have increased significantly since 1994. These parameters are usually inversely related and thus other processes about which we know very little must be influencing the relationship between water clarity and phytoplankton biomass.
6. The DCM can contain up to 70% more chlorophyll *a* than in the upper 10 m layer. This represents a substantial amount of the algal biomass which is not being assessed in the monitoring reports, although it is measured as chlorophyll fluorescence at every sampling occasion. More information is required on relationship between the DCM and nutrient concentrations in the hypolimnion and how the DCM affects the VHOD estimate in the lake.

6. Summary

- Using a linear regression through all data, the annual mean chlorophyll *a* concentration in the upper 10 m of water column in Lake Taupo, as an indicator of phytoplankton biomass, has increased at a rate of $0.013 \pm 0.011 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P=0.016$, $r^2 = 0.0175$, $n = 331$) over the 19 year monitoring period.
- There is a substantial deep chlorophyll maxima (DCM) below the thermocline (40 m) in the lake during spring and summer with estimated chlorophyll *a* concentrations up to 450% higher than the chlorophyll *a* concentrations measured in the upper 10 m. Assessment of the DCM over a 5 year period suggests that it often contains a high proportion of the total phytoplankton biomass and occasionally may account for more than 70% of the total biomass in the lake. The DCM was present through the 2012/13 spring and summer period.
- It has become apparent that the increase in chlorophyll *a* concentrations in the top 10 m may not be a linear trend. The annual mean chlorophyll *a* data from 1994 to 2003 increased at a statistically significant rate of $0.087 \pm 0.029 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.001$, $r^2 = 0.857$, $n = 10$), but since 2000 there has been a non-statistically significant trend of decline at a rate of $0.012 \pm 0.022 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P = 0.26$, $r^2 = 0.105$, $n = 14$). These latter data suggest an improvement in lake water quality, but may also indicate a redistribution of phytoplankton production to the DCM.
- After 2000, peak chlorophyll *a* concentrations in winter have become highly variable, ranging between 1.5 and 3.0 mg m^{-3} with a weakly statistically significant trend of decline at a rate of $0.052 \pm 0.059 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P = 0.075$, $r^2 = 0.240$, $n = 14$).
- Algal species composition in winter 2012 was dominated by diatoms, *Asterionella formosa* and *Fragilaria crotonensis*, each initially accounting for about 40% of the biovolume in the upper 50 m of the water column. *Asterionella* became dominant for much of the 2012/13 monitoring period. The dinoflagellates, *Gymnodinium sp.*, *Gonyaulax sp.*, and *Peridinium sp* increased in abundance through summer 2013 with changing dominance between the three species. Cyanobacteria (blue-green algae) were always present in low numbers in the upper water column throughout the 2012/13 monitoring period, with *Dolichospermum planctonica* (formerly *Anabaena planctonica*) being the most common species, which reached high abundance in November 2012 and February 2013, and then briefly became the dominant species in April 2013.
- Although similar in species composition to the phytoplankton assemblage in surface waters, phytoplankton samples collected from the DCM by van Dorne sampler from a depth of 50 m were, on occasion, lower in biovolume. The low biomass compared with the DCM as indicated by the chlorophyll fluorescence profile was probably due to the van Dorne sampler not collecting water from the centre of the DCM peak.

- There was a statistically significant trend of increase in the total mass of NO₃-N in the hypolimnion before winter mixing of around 4.3 t yr⁻¹ ($P < 0.05$, $r^2 = 0.15$, $n = 26$) which was slightly lower than determined in the previous year. The amount of NO₃-N in the hypolimnion in autumn 2013 was around 30 t higher than the previous year.
- The net accumulation rate of NO₃-N in the hypolimnion below 70 m was in the order of 2 t d⁻¹ in the early 2000s but has slowly decreased to around 1.5 t/d in 2012/13. The net accumulation rate of NO₃-N in 2012/13 was 20% higher than the 2011/12 rate of 1.23 t d⁻¹. Regression analysis shows that there was a weak statistically significant trend of increase in the rate of 0.026 ± 0.018 t d⁻¹ each year ($P < 0.007$, $r^2 = 0.299$, $n = 23$) over the last 38 years, but a decrease since 2000.
- There was essentially no long term change in the whole lake TN, with a mean of 3294 t. However, the TN content of the lake in spring 2012 was only 2895 t, an increase of around 675 t since the previous year.
- The 2012/13 net VHOD rate for the period from September 2012 to January 2013 was 29.6 ± 7.1 mg m⁻³ d⁻¹ (mean \pm 95% confidence limit) which was more than 14 mg m⁻³ d⁻¹ higher than the previous year at 15.24 ± 7.34 mg m⁻³ d⁻¹.
- There has been a statistically significant ($P < 0.0001$, $r^2 = 0.74$, $n = 15$) increase in the VHOD rate of about 1.2 mg m⁻³ d⁻¹ each year since the low in 1999, suggesting a decline in lake water quality. While the period of the regression analysis is selected from lowest to highest, and thus does not reflect a long-term trend in Lake Taupo, this sustained increase in VHOD over a 15-year period implies a change in the export of organic carbon to the hypolimnion over this period, either from external inputs (i.e., land-use effects), or internal sources such as primary production and sediment resuspension within the lake, or a combination of both external and internal sources.
- Nutrient concentrations (DRP, NH₄-N, and NO₃-N) in the upper water column were generally comparable with concentrations since 2003 and are similar to historical concentrations before Mount Ruapehu erupted in 1995. However, since 2006/07 there have been elevated NH₄-N but low NO₃-N concentrations in the upper water column through summer and autumn 2013. In winter and autumn 2012 there were elevated DRP and NO₃-N concentrations in the upper water column. In autumn 2012 there was a series of hydrothermal events, associated with the eruptions of Mount Tongariro, which resulted in elevated DRP, NH₄-N and NO₃-N concentrations in the surface waters. Elevated DON concentrations in the surface waters were also associated with these hydrothermal events.
- Maximum surface water temperatures are typically in the range of 17 °C to 21 °C with the warmest months being February and March. There is an apparent cyclical pattern in maximum water temperatures indicating cooler summers between 1999 and 2007 and warmer summers before and after. The maximum surface water temperature in summer 2013 at 20.4 °C, was around 1.4 °C

warmer than the previous year but was comparable the four years before that. This temperature increase can be attributed to the drought during summer 20-13.

- Bottom water temperatures rose to 11.05 °C during the 2012/13 monitoring period.
- Water clarity during summer 2012/13 was mostly around 16.0 m, but peaked at 21 m in March 2013. The lower clarity in January and February 2013 may have been associated with Aeolian deposition of fine sediment in the lake during the drought or entrainment of lake bed sediment with hydrothermal events. Water clarity dropped from the maximum 19 m on 19 December 2012 to 15.8 m on 20 January 2013. A sudden reduction in clarity from 21 m on 6 April 2013 to 14 m on 20 April 2013 was associated with a hydrothermal eruption event which appeared to entrain sediment into the surface waters.
- From 2000 to 2007, winter minimum clarity occurred around August. Since 2007, minimum clarity occurs around October, two months later. For the 2012/13 monitoring period, the minimum clarity was in October 2012.

In a previous annual report (Gibbs et al. 2002), three trends in the data were identified that were of concern with respect to the water quality of Lake Taupo. These were: increasing phytoplankton biomass in the upper 10 m; increasing NO₃-N mass in the lake hypolimnion prior to winter mixing; and an increasing range in the variability of water clarity.

While these trends are still present in the whole data set, there are indications that water quality may be beginning to stabilise e.g., mean annual chlorophyll *a* concentrations have been more or less steady since 2000. In contrast, however, the VHOD rates have been increasing since 1999, suggesting that the water quality has declined since then. The very high VHOD rate in 2012/13 adds further weight to this argument.

These contrasting indicators are not mutually exclusive. The steady or weakly significant decline in mean annual chlorophyll *a* concentrations since 2000 is consistent with the nearly constant annual maximum hypolimnetic concentrations of DRP and NO₃-N in autumn for the last 8 years (Figure 18). These nutrients become available for algal growth after winter mixing. However, the persistent increase in the net VHOD rate indicating an increase in oxygen demand implies a change in the loading of organic carbon on the lake. The temporal disassociation of the chlorophyll *a* maximum in July-August from the minimum water clarity in October (Gibbs 2011) suggests that the carbon load through suspended sediment inputs from land may have increased in spring months when high rainfall occurred. There is also a substantial amount of carbon associated with the phytoplankton biomass in the deep chlorophyll maxima which is likely to have an effect on the VHOD rate as the phytoplankton senesce and decompose.

7. Acknowledgements

This report was made possible by the team effort of Philip King and Heath Cairns of the Taupo Harbourmaster's Office, and Eddie Bowman (NIWA Rotorua) who have collected the data. Much of the success of this monitoring programme is attributable to the extra effort by Eddie and the team.

Water samples were processed in the NIWA chemistry laboratory and analytical results were provided by Graham Bryers, Margaret McMonagle, Cara Mackle and team. Quality control was provided by Mike Crump, Lab Manager.

Phytoplankton dominance and enumeration results were provided by Karl Safi and Helen Brider from NIWA Algal Services.

8. Glossary of abbreviations and terms

BOD	Biochemical Oxygen Demand: the rate of oxygen consumption associated with biological decomposition and chemical processes and in the water column.
VHOD	Volumetric Hypolimnetic Oxygen Demand: the net rate of oxygen loss associated with biological, chemical and physical processes in the hypolimnion of a lake in the absence of a temperature change.
Phytoplankton	Microscopic free-floating aquatic plants (algae).
Cyanobacteria	Blue-green algae. These are potentially toxic. They can adjust their depth in the water column using small gas bladders (gas vacuoles), and some species can use (i.e., fix) atmospheric nitrogen for growth when nutrient nitrogen in the water column is depleted.
Zooplankton	Small to microscopic free-swimming aquatic animals which graze on phytoplankton or smaller zooplankton.
Biomass	The living mass of the phytoplankton or zooplankton populations.
Thermal stratification	Separation of a water column into two layers by temperature – warmer water on top.
Thermocline	The boundary zone or temperature gradient between the two layers in a thermally stratified water column.
Epilimnion	The upper water column in a thermally stratified water column.
Hypolimnion	The lower water column in a thermally stratified water column.
Metalimnion	The thermocline zone — of variable thickness.
Euphotic zone	The upper water column in which there is sufficient light for photosynthesis and hence phytoplankton growth.
Euphotic depth	Lower limit of phytoplankton growth where light levels are 1% of surface irradiance.
Hydrothermal eruption	Sudden release of superheated water from volcanic vents in the bed of the lake. The source is most likely infiltrating lake water heated by hot rocks. The heated water includes dissolved salts leached from the rocks and sediment.
Nutrients	Essential dissolved inorganic nitrogen and phosphorus compounds which can be used directly by plants for growth.
Ammoniacal nitrogen	Sum of ammonium ion (NH_4^+) plus free (unionised) ammonia (NH_3). Some amines (NH_2^-) may be included as interference during analysis. Symbol, $\text{NH}_4\text{-N}$.
Nitrate nitrogen	Used in this report as the sum of nitrate (NO_3^-) plus nitrite (NO_2^-). Symbol, $\text{NO}_3\text{-N}$.
DIN	Dissolved Inorganic Nitrogen: the sum of $\text{NH}_4\text{-N}$ + $\text{NO}_3\text{-N}$.
DON	Dissolved Organic Nitrogen: the soluble nitrogen other than DIN.
PN	Particulate Nitrogen: includes phytoplankton and other detritus.
TN	Total Nitrogen: Sum of DIN + DON + PN.
NO_x	Gaseous oxides of nitrogen, including N_2O , NO , NO_2 .

Appendix 1. Site map, sampling strategy and methods

Site map

Lake monitoring sites were originally established using land-based markers (Figure 23). These have now been defined using GPS and corrected for curvature using WGS84 convention.

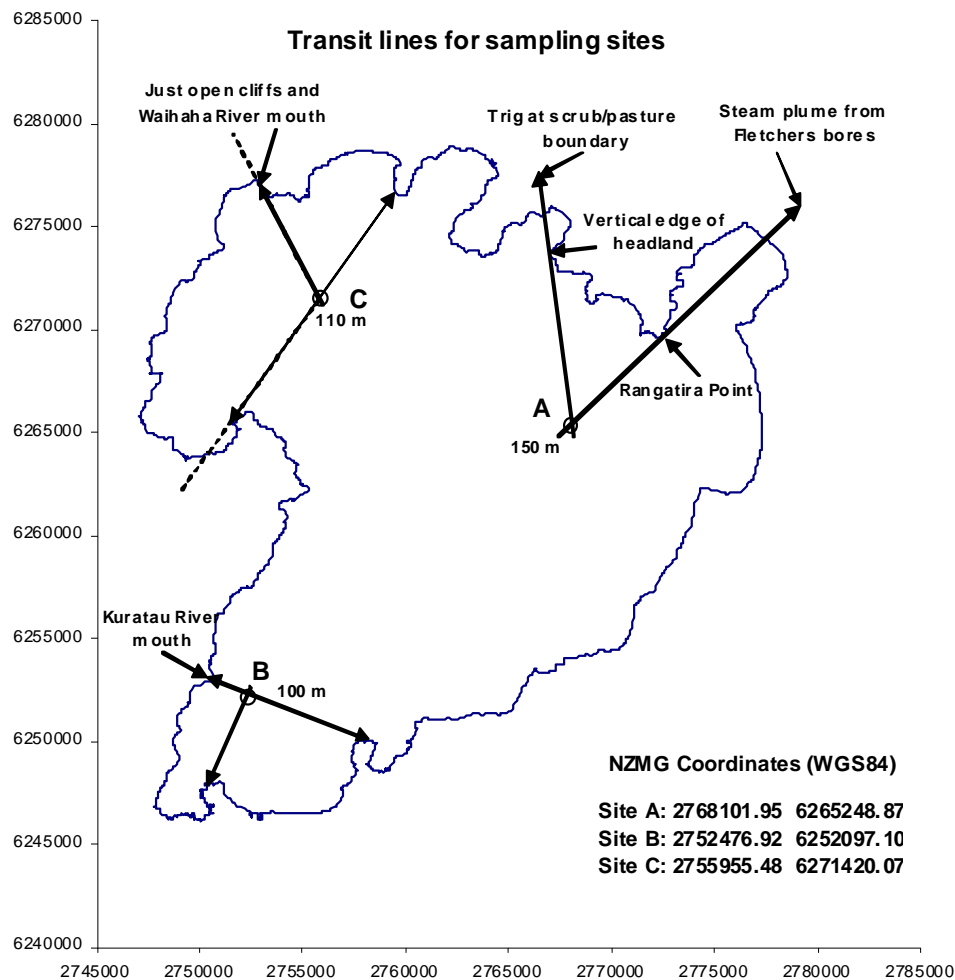

Figure 23: Site map of Lake Taupo. Site map of Lake Taupo showing location of the routine monitoring site at mid lake (A). Two additional sites at Kuratau Basin (B) and the Western Bays (C) were sampled between January 2002 and December 2004 inclusive. Data from those sites have been retained with the Site A data presented in the appendices. Map coordinates are in NZ Map Grid with WGS84 correction. Lat. Long WGS 84 corrected co-ordinates of "Site A" are 38° 46'.810 S; 175° 58'.440 E.

The following section has been copied from Gibbs 1995, and modified after 1998.

Methods

The sampling site was selected in the central basin of Lake Taupo (Site Map) with a water depth of about 160 m. This site is more than 5 km from the nearest land and is exposed to both the north-south and east-west axis of the lake.

To calculate VHOD requires two measurements each year far enough apart in time for a measurable change to occur in the DO concentrations in the hypolimnion of the lake. Details of the procedure and limitations of this measurement are described by Vant (1987). For the monitoring of Lake Taupo, which mixes briefly in winter between July and August, the initial sampling time was selected to be in October, to give sufficient time for thermal stratification to establish a stable hypolimnion. The final sampling time was selected to be in April, before lake cooling causes the downward movement of the thermocline which precedes the winter mixing.

At each of these biannual samplings, a detailed profile of DO and temperature was measured. Prior to 1998, measurements were made at 1 m depth intervals through the full depth of the water column using an in situ recording Applied Microsystems STD-12 profiler fitted with a Royce DO sensor, and compared with manual measurements of DO and temperature made at 10 m depth intervals from the surface to the bottom of the lake using a Yellow Springs Instrument (YSI) model 58 dissolved oxygen meter fitted with a stirred Model 5739 probe on a 160 m cable. Subsequent to 1998, a Richard Brancker Research (RBR) model TD410 conductivity-temperature-depth (CTD) profiler fitted with a stirred YSI model 5739 DO sensor was used. In January 2002, the TD410 CTD profiler was upgraded to an RBR model XR420f freshwater CTD profiler fitted with the YSI model 5739 DO sensor and a Seapoint chlorophyll fluorescence probe. The DO sensor was calibrated regularly by NIWA, Rotorua staff and chlorophyll fluorescence was converted to chlorophyll *a* from extracted chlorophyll *a* analyses of water samples collected beside the profiler.

In January 2008, the XR420f profiler was upgraded to a RBR model XR620f freshwater profiler/logger with improved sensitivity. The new profiler is fitted with a Sea Point chlorophyll fluorescence probe and a Li-Cor underwater photosynthetically active radiance (PAR) sensor to measure in situ light levels and light extinction (K_d) associated with the vertical distribution of algal biomass within the lake water column. In the new system the YSI dissolved oxygen (DO) sensor was replaced with an Oxyguard DO sensor, with a temperature sensor, fitted to a separate RBR logger attached to the profiling frame.

Cross-calibration between the two profilers confirmed the quality of the data and the XR420f has been retained as a back-up.

The following parameters were also measured as profiles from water samples collected using a van Dorn water sampling bottle starting at 1 m and then at 10 m intervals from 10 m to the bottom of the lake:

DO, chlorophyll *a*, dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), total phosphorus (TP), nitrate+nitrite nitrogen ($\text{NO}_3\text{-N}$)*, ammoniacal nitrogen ($\text{NH}_4\text{-N}$), dissolved organic nitrogen (DON), particulate nitrogen (PN), total nitrogen (TN), urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC) and dissolved organic carbon (DOC). (* Little, if any nitrite is ever found in the Lake Taupo water column, hence the use of $\text{NO}_3\text{-N}$).

Note: TN and TP values are the summation of all other N and P components, respectively, excluding Urea-N which is part of the DON component.

Additional parameters measured but not as complete profiles were:

Water clarity (by Secchi disc depth) and algal species composition and abundance on water samples from 1, 10, 50, 100, and 140 m.

Determinations on the water samples were made with the standard methods routinely used for freshwater analysis by NIWA on a Lachat FIA flow injection analyser.

Algal species composition and abundance were obtained by settling a measured volume of sample (up to 100 mL) in Utermöhl (1931) tubes and counting on an inverted microscope. Biovolume was estimated from cell volume tables calculated from the cell dimensions of each species. Dominance was estimated from relative biovolumes with the highest biovolume assigned dominance 1 as most common and the lowest biovolume assigned the dominance 10 as rare. Professional judgement was used to relate dominance between samplings.

Since 2007, dominance is no longer used and the algal data are reported in cell counts and biovolume.

Data for the long term monitoring programme were scheduled to be collected from the mid-lake sampling station at 2 weekly intervals. The practicality of achieving this target was limited by the weather and in reality data were generally collected at about 2-3 weekly intervals. Parameters measured were:

DO and temperature profiles at 1 m depth intervals to the bottom of the lake by RBR profiler, water clarity as Secchi disc depth, and a 10 m tube water sample was collected for measurement of chlorophyll *a*, NO₃-N, NH₄-N, TN, DRP, TP, and algal species dominance. Chlorophyll fluorescence, conductivity, and PAR data from the profiler are archived but not routinely included in this report.

From 2000, near-bottom water samples from 150 m were collected using a van Dorn water sampling bottle and analysed for DRP, NO₃-N, and NH₄-N.

Data handling and less than detection limit values

All data in this report have been processed and manipulated on Excel spreadsheets. Data is rounded using the Excel protocol to an appropriate number of significant numbers based on the need for detailed knowledge tempered with the confidence in the precision and accuracy of the analytical methods used. This treatment may lead to small differences between electronic copies of the data and the values presented in this report.

The difference between the written report and the Excel spreadsheet of essentially the same data is the treatment of the less than detection limit (<DL) results. The data have in the past been written as <DL or <DL(value). For statistical analysis the excel spreadsheet replaces <DL with 0 or uses the value in brackets in place of 0. Although it is recognised that the former action will be in error, the use of the value in brackets requires some justification.

In discussion with Burns Macaskill, Graham McBride, and Mike Crump from NIWA on this issue, the following conclusions were reached:

- In general the data is reported as a series of results from analytical methods which have known limitations and precision. The raw number is reported where ever possible so that the user can draw their own conclusions about the reliability of the "last significant figure" on any result when performing data manipulations.
- The real problem arises at very low levels and the result obtained is less than the method's prescribed DL. The problem is not so much the result obtained but what to do with it which in turn raises the question 'What do we mean by detection limit'?
- In the book "Statistical methods in water resources" Helsel & Hirsch 1992 [Studies in Environmental Science 49, Elsevier], and chapter 13 "Methods for data below the reporting limit" it is pointed out that the 'detection limit' is variously known as the 'reporting limit' or the 'limit of quantitation'. If no other value is available, there are 3 main options: call it zero (which is clearly an under estimate), call it the detection limit (which is clearly an over estimate), or call it half the detection limit (which gives a 50:50 chance of an over or under estimate). The choice then is one of 'which convention do you wish to use'. In the written reports, I have treated the <DL as zero for summation purposes. This is an under estimate which I should have noted on each report page so that anyone using that data is aware of the convention used.
- An alternative approach is to say that, before the sample is analysed, the DL is the predicted minimum level that will be found using the stipulated method. However, once the sample is analysed the result is what was actually measured and may be <DL on the day of analysis. As it is an actual analytical result, that value (reported in brackets) should be reported even though it is <DL. This implies that the method DL is in reality a reporting level or level of confidence.
- The "DL" was derived for the Lake Taupo data, on each analytical occasion, from a series of blanks and 1ppb standards run with the samples. The "DL" is set as 3 times the SD of the 1 ppb standard. This is actually a limit of confidence. All samples are run in duplicate and the mean of the two results becomes the concentration reported.
- With the introduction of the Lachat FIA system, the limits of detection have been confidently lowered to the point where replicate results may often be <DL. In these instances, in the written report, the value is reported as <DL(result). In the past I have still used the <DL = 0 convention in summation for the TN and TP data. This is obviously wrong and the actual result should be used, as is done in the electronic spreadsheet.

In this report the analytical value 'on-the-day' has been used wherever possible. Data reported as <DL use the <DL = DL/2 convention. Past data have not been corrected or altered to conform to this protocol.

These technical details are incorporated in this annual report so that data users are aware of how the 'DL' or confidence limit was set and how the values <DL are treated when performing data manipulations.

There is still the question of how to deal with numbers where the result has been simply reported as <DL. The use of the DL/2 convention is probably closer to reality than the DL = 0 convention.

Helsel & Hirsch suggest an alternative method for estimating a value in the <DL range. If there is sufficient real data >DL, a probability curve can be derived and extrapolated around the DL to generate the most probable number for the <DL value.

Statistical methods

Copied from Gibbs (2000).

In this report we have used linear regressions and associated statistical tests to examine trends. The key result of these procedures is the coefficient of determination (r^2), which measures the amount of variability in the data that is accounted for by the regression. Another is the P -value². This can be used as a weight of evidence against the hypothesis that there was in fact no trend. This weight is strong when P is small, meaning that a trend at least as large as that measured could have occurred merely by chance—we have only a limited number of data from which to infer the strength of any trend, so our measurements always are uncertain to some degree. So if P is low enough (taken as less than 5% in this report, which is the usual practice), it is conventional to say that the measured trend is "statistically significant", and that convention is followed in this report. However, it is important (and often not realised) to note that the P -value cannot be used as an absolute weight of evidence. This is because it tends to decrease as the number of samples taken in a given period is increased. For example, when we plot monthly Secchi disc depth data from 1994–2001 (Figure 3A, Gibbs 2000) with these 93 data we obtain a statistically significant result (because $P < 0.05$)—even though the coefficient of determination was only $r^2 = 0.0445$. When we plot the minimum winter clarity over this period we then have only 7 data. In this case (Fig. 3B, Gibbs 2000) we happen to have the same measured trend slope with a much higher coefficient of determination ($r^2 = 0.464$), yet the result is not statistically significant (because $P = 0.09$). This is entirely because of the reduced number of samples in the winter minimum case.

What this makes clear is that the P value is useful as a relative weight of evidence when comparing datasets of the same size, but it has no evidential meaning when comparing results from datasets of very different sizes.

² It is defined as the probability of obtaining a trend at least as extreme as was obtained if in fact there was no trend at all.

Appendix 2. The calculation of VHOD rates

Copied from Gibbs 1995.

Rationale

In the strictest terms, VHOD can only be calculated for a lake which has thermally stratified and the resultant thermocline provides an effective barrier against re-oxygenation of the hypolimnion. The measure of the barrier efficiency is the rate of heating of the hypolimnion following stratification as heat will be transferred across the thermocline at a similar rate to oxygen.

In Lake Taupo, the thermal inertia of the hypolimnion is so great that heating during the stratified period is typically about 0.2 °C and never more than 0.4 °C over a 200 day period. While this would seem to meet the temperature criterion, in a lake that large, oxygen can be transferred into the hypolimnion by mechanisms other than diffusion.

Wind induced mixing may increase turbulent diffusion across the thermocline as would an internal seiche on the thermocline. Both of these mechanisms would transfer heat. The penetration of the thermocline by an under-flowing density current would entrain oxygenated surface water into the hypolimnion with that flow. As the density current must be colder than the thermocline to plunge through it, there is no heat transferred with this mechanism.

In Lake Taupo the Tongariro River water is always colder than the lake surface water and for at least 9 months of the year it is also colder than the minimum lake water temperature of 10.3 °C. Thus, during most of the stratified period, the Tongariro River flows directly into the hypolimnion entraining oxygenated surface water with it. The amount of surface water entrained has been estimated to be about 10 times the river discharge. The amount of oxygen transported in this way is likely to be more than 200 tonnes per day.

Clearly this is a substantial oxygen input which invalidates the concept of the thermocline forming an oxygen barrier for purposes of calculating the VHOD. The true VHOD may only be calculated during mid-summer when the Tongariro River flows deep into the epilimnion but does not penetrate the thermocline.

The data collected to date indicates that hypolimnetic oxygen depletion occurs throughout the stratified period - with or without the density current re-oxygenation - and hence the value obtained from a VHOD calculation over the whole stratified period is the net VHOD rate taking all the factors affecting the hypolimnion into account.

As the data from 1996/97 shows, the density current also advects dissolved organic nutrients with it. Hence, management strategies which affect the Tongariro River also impact on the lake. Hence it is appropriate to use the net VHOD rate for inter-annual comparisons rather than the true VHOD rate calculated only through mid-summer.

Method of calculation

The following is the method used to calculate the net VHOD rate for Lake Taupo.

Requirements: Microsoft Excel spreadsheet or equivalent.

Although the thermocline in Lake Taupo is usually at about 40 m, the isothermal water column lies below 70 m. To accommodate the gradient across the thermocline, the net VHOD rate calculation only uses oxygen data from below 70 m.

To calculate the mean oxygen concentration in the water column below 70 m, the DO concentration at each 10 m depth increment is multiplied by the volume of the 10 m slice it came from. This assumes rapid horizontal mixing and minimal vertical mixing to extrapolate one DO value across the whole lake. Historical data from multiple sites would suggest that this is a reasonable assumption.

The slice volumes (hypso-graphic volumes) for Lake Taupo have been calculated for 10 m thick layers centred on the 5 m point of each slice i.e., 75, 85, 95, 105 m etc. The DO measurements are made at 10 m intervals i.e., 70, 80, 90, 100, 110 m etc.

The mass of oxygen in each 10 m slice is the average of the DO concentration at the top and bottom of a slice multiplied by the slice volume. i.e., for the 70 - 80 m slice the calculation is:-

$$\text{DO Mass}_{70-80\text{m}} = ((\text{DO}_{70\text{m}} + \text{DO}_{80\text{m}}) \div 2) \times \text{Volume}_{70-80\text{m}}$$

For each profile date:

Compute the DO mass for each 10 m slice between 70 m and 150 m and sum the results as the total mass of DO in the hypolimnion below 70 m. Sum the slice volumes below 70 m as the total volume of the hypolimnion below 70 m.

The volume weighted mean DO concentration is the total DO mass value divided by the total volume value.

Use the sequential day number or equivalent to construct a time series of volume weighted mean DO concentrations over the stratified period and use the Excel regression analysis tool to obtain the $y = ax + b$ straight line fit for these data.

As the DO data are in g m^{-3} , the value of 'a' is in $\text{g m}^{-3} \text{d}^{-1}$. Multiply 'a' by 1000 to get the net VHOD rate in $\text{mg m}^{-3} \text{d}^{-1}$. The negative sign from the regression equation indicates a loss rate. By convention VHOD is always a "loss" term and thus the negative sign is omitted when reporting net VHOD rates.

The hypso-graphic volumes and upper surface areas of the 10 m slices through the whole depth of Lake Taupo are listed at the end of this section.

Statistical evaluation of the VHOD rate

From the 1999-2000 monitoring report (Gibbs 2000), the VHOD rate is expressed as the calculated net VHOD rate \pm the 95% confidence limit. This gives a meaningful estimate of the range within which the VHOD rate lies and is more appropriate than the standard deviation on the data or a standard error estimate on the regression coefficient.

Table 2: Lake Taupo Hypsographic Data used in the Net VHOD RATE calculation.

Slice depths (m)	Volume of slice (km ³)	Upper surface area of slice (km ²)
0 - 10	5.849359	600

Appendix 4. Nutrient data

Includes accumulated 10-m tube data since 1994. Blank cells represent missing data.

For completeness, 10-m tube data collected from the Kuratau Basin (site B) and Western Bays (site C) from January 2002 to December 2004 are included as separate sheets following the mid-lake data from site A for those years.

In the spring/autumn profile data, two different analytical methods are used to measure particulate nitrogen:

1. a wet digestion method involving high temperature refluxing in digestion mixture [persulphate / sulphuric acid / Selenium catalyst] for 3 hours followed by colorimetric determination of the nitrogen as the ammoniacal form, and
2. a CHN combustion method which converts all nitrogen compounds to N_2 gas in a furnace at $\sim 1000^\circ C$ to be measured in a thermal conductivity detector.

Particulate nitrogen analysed by the wet digestion method may not include some refractory nitrogen components which may be detected by the CHN combustion furnace method. Consequently the PN value from the CHN combustion furnace method should always be greater than or equal to the PN value obtained by the wet digestion method. Occasionally they are reported as less than the wet digestion method value in which case the wet digestion value should be regarded as correct. The cause of this difference is unknown but may be associated with the presence of low molecular weight organic nitrogen compounds lost during the drying step before combustion. The PN values for the time series data are all from wet digestion method analyses and hence are directly comparable with the profile data.

Low level NH_4-N results are likely to be subject to interference from low molecular weight

From February 2002, DRP, NO_3-N , and NH_4-N were measured on a Lachat Flow Injection Analysis (FIA) system but using essentially the same chemistry as previously used on the Technical Auto-Analyzer system. The reported detection limits for these nutrients remains the same at 0.5 mg m^{-3} for DRP and NO_3-N , and 1 mg m^{-3} for NH_4-N , however, the greater precision of the FIA system provides confidence in reporting results to a lower level as an indication of likely absolute values near zero. Such values are provided as an indication only and the true value should be expressed as less than the detection limit. TN and TP values are the sum of all N and P components, excluding Urea-N which is part of the DON component. All analytical values 'on-the-day' are used wherever possible or $<DL = DL/2$ for summation in TN and TP. See Appendix 1 for discussion on detection limits.

The DON value for 5/08/2000 was corrected from 12 to 43.5 in March 2006. This was a transcription error from the original analytical result sheet.

From October 2009, chlorophyll *a* concentrations collected by van Dorne sampler from a depth of 50 m have been included in the data set as an indication of the biomass in the DCM. However, because the DCM moves up and down during the year, the fixed depth samples from 50 m may not always be in the centre of DCM.

Lake Taupo cumulative database of 10m tube sample data from October 1994 to September 2002.
 Samples collected from central lake site.

NH₄, NO₃, DON, Urea all as N * = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

					DO sensor failed; indicative data from 14 March																
NH ₄ , NO ₃ , DON, Urea all as N					* = PN by wet digestion method, ** = PN by combustion furnace method.																
Detection limits: DRP 0.5; NO ₃ -N 0.5; NH ₄ -N 1.0 mg m ⁻³																					
New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.																					
FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO ₃ -N, and NH ₄ -N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, UREA all as N

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

* = analysed by wet digestion method, ** = analysed by CHN combustion furnace method.

Appendix 5. Phytoplankton data

In this report phytoplankton abundance is reported in cell counts per ml and biovolume per ml. In the previous system reporting only algal dominance, "Dominance" (rank 1 = dominant to rank 10 = rare), was calculated from algal biovolume. For continuance of the Dominance format, the species composition is ranked by biovolume.

Note: reporting counts as cells per ml rounded to a whole number may result in cell counts of "0" despite a large biovolume where the algal species is large or colonial e.g., *Botryococcus braunii*

The new algal data has been added to this report and the data from the previous year retained to accumulate, as has been done with temperature, DO, and nutrient data.

Note: *Leptolyngbya* sp. cells on 07/09/2009 (highlighted) are likely to have been washed off something rather than being local in 150 m of water.

Name changes:

Anabaena has changed to *Dolichospermum* as of August 2009. It will initially be referred to as follows: *Dolichospermum* sp. (formerly; *Anabaena* sp.).

Units of biomass are listed as " μm^3 " in the following tables. The units are actually μm^3 /mL.

From the 2010/11 monitoring period, phytoplankton data have been provided from a depth of 50m, which generally coincides with the deep chlorophyll a maxima in the lake. This sample was collected by van Dorne bottle and is distinguished from the 10-m tube sample by being placed in a separate table for the same dates as the 10-m tube sample.

Lake Taupo phytoplankton enumeration (10-m tube) 2009-10

Cell counts and biovolume

Cells per ml numbers may be affected by rounding

Appendix 6. Historical data

Historical data held by NIWA has frequently been referred to and included in some analysis or comparison of the data from the long-term monitoring programme. To ensure that these data are always readily available, copies of the relevant historical data are included in this report. These data are the spring and autumn profiles of NO₃-N and DRP from 1974 to 1990 extracted from archived data books. The nitrate data for 27 September 1979 was taken from Vincent (1983). Subsequent data can be found in the previous appendices.

Note that the profiles given are aligned with the spring data above the corresponding autumn data, by date. Note also that the early profiles were to a depth of 110 m rather than 150 m. Also, as there was no March or April data collected in 1976, for completeness, the last valid profile in that series (12 January 1976) has been included.

The elapsed time given is the number of days between the spring profile in about October and the autumn profile in March/April of the following year. The average elapsed time between the two samplings across all data from 1974 to 2006 is 165 days.

The historical data also include an un-paired profile from July 1987. As there were no data for April 1987 and the lake was still stratified in July, when the next period of monitoring began, the July 1987 may be used as an indication of the total mass of nutrient accumulation in that year. Because these data are for an un-paired profile in July and not April, if the data are converted to rate estimates the assumption must be made that there was no spring carryover and the elapsed time is longer, being estimated as the average elapsed time plus three months.

Because the 1976 and 1987 data are for periods other than spring (October/November) to autumn (March/April), these data points have been excluded from any regression analysis of time-series data although the data points have been plotted as an indication of levels/rates for those years.

Historical data from Site A in Lake Taupo
